Night Medical Service in Paris.—This service was organized in 1876, and consists at present of 739 physicians and 308 midwives. The number of visits made increased from 3,616 in 1876, to 9,895 in 1883. In 1884, notwithstanding a large proportional increase during the last quarter by reason of the cholera, there was a total of only 8,712. Of the calls during the last quarter of 1884, 145 were for cholera, 11 for cholerophobia, 273 for cholerine, and 237 for various other intestinal disorders.

Too Many.—A female of the human species, living in Algeria, gave birth not long ago to five boys in one litter, three of whom were at last accounts alive. Possibly the others were drowned.

Progress of Medical Science.

The Relief of Pyloric Stenosis.—Until within the past six years the above condition was regarded as beyond the domain of surgical interference, and with the diagnosis, stenosis of the pylorus, the fate of the patient was irrevocably sealed. Internal medicine offers absolutely no hope to the unfortunate sufferer from pyloric stenosis, until Péan, in 1879, performed pylorectomy for the relief of pyloric disease, and ushered in a new era in abdominal surgery. Dr. Randolph Winslow, of Baltimore, in *The American Journal of the Medical Sciences* for April, 1885, has collected and analyzed all the recorded cases, eighty-five in number, of operative interference for the relief of pyloric disease. He presents the following valuable deductions: 1. In cancer of stomach not producing stenosis, anodynes should be given in quantities sufficient to relieve distress, and no operation should be performed. 2. Pylorectomy for carcinoma is followed by seventy-six per cent. mortality, hence it should only be very exceptionally performed in those cases where, with marked stenosis, the pylorus is not adherent to the neighboring organs, and the patient is young and fairly strong. 3. In other cases of carcinomatous stenosis, as only very temporary benefit can be obtained, gastro-enterostomy should be performed. 4. In cicatricial stenosis digital divulsion should be performed, but if this is impossible owing to great thickening of the walls, resection in those who are well nourished, and gastro-enterostomy in the debilitated will both be followed by good results. 5. Hemorrhage or perforation from ulcer or other cause than stenosis, does not present indications for pylorectomy. 6. Duodenostomy, gastrostomy for the passage of a tube, and complete gastrectomy should all be replaced by gastro-enterostomy. In the same journal Dr. J. M. Spear, of Cumberland, Md., reports a case of partial pylorectomy in a blacksmith, aged forty, who suffered from cicatricial stenosis of the pylorus. The operation was a modification of Billroth's, and required one hour and a half for its performance. The tumor was not adherent. Death ensued in two and a half hours, from collapse. In the opinion of Dr. Spear the case was an eminently proper one for operation, but it should have been performed at an earlier period in its history.

Membranous Croup; Diphtheritic Croup; True Croup.—Dr. J. Lewis Smith holds that inflammation of the laryngeal and tracheal surface, whatever its cause, whenever it reaches a certain grade of severity, may be attended by the exudation of fibrin and the formation of a pseudo-membrane, but such a result more frequently occurs in the inflammation caused by diphtheria than in that produced by other agencies. In diphtheria a moderate laryngo-tracheitis is attended by the pseudo-membranous formation. Dr. Smith's experience leads him to believe that not more than one in eight cases of croup has recovered by medicinal treatment which began in the first week of diphtheria, and in which the symptoms were so pronounced as to indicate more or less laryngeal stenosis. The exudation in the first week of diphtheria, or in its active period, occurs so rapidly, and in such large quantity, that no one of the medicinal agents or modes of treatment, which physicians commonly prescribe, is sufficiently prompt in its action to prevent the formation of the pseudo-membrane to an extent that soon endangers life. Croup occurring in the second or third week of diphtheria, since it is attended by less abundant and less rapid exudation than when it occurs during the acute stage, can be more successfully treated under the persevering use of solvent inhalations, and a larger proportion than one in eight, perhaps one in three, recovers by the early and continuous, or almost continuous, use of inhalations. Still the mortality is so large, and the suffering so great in croup, at whatever stage of diphtheria it occurs, that we cannot rely on the slow action of medicines or inhalations, and surgical treatment is in most instances required to diminish the suffering, and afford the best chances for saving life. Under the head of medicinal treatment Dr. Smith strongly recommends trypsine as a solvent of false membrane. Of calomel, he says: The experience of many physicians justifies the belief that mercury, and especially calomel, employed within certain limits in the commencement of a pseudo-membranous inflammation does exert some controlling action on this disease. That it did much harm formerly when physicians prescribed it as freely as we now employ potassium chlorate, to the extent in many instances of increasing the cachexia and causing mercurialism, should not deter from its judicious use. In the ordinary form of diphtheria he would not advise the use of calomel, or would limit its employment to one or two doses of six to ten grains in the commencement of the disease in robust cases. But in croup, since the danger is not from the cachexia or blood-poisoning so much as from the laryngeal stenosis, which is apt to develop rapidly, that medicine is indicated, and should be prescribed, which most strongly retards the exudative process, and aids in liquefying and removing the pseudo-membrane; provided that it produce no deleterious effect which renders its use inadmissible. Hence it is proper to prescribe calomel in larger doses and for a longer time in the treatment of croup, than in other forms of membranous inflammation, if it fulfil the indication, as it seems to in a measure. Dr. Smith states that we can claim for tracheotomy judiciously performed, and at a sufficiently early stage, the cure of one in every three patients in the average.—*American Journal of the Med. Sciences*, April, 1885.

The Diagnosis of Submersion during Life or after Death.—The Paris correspondent of the *London Lancet* writes that, struck with the divergence of opinion among authors as to the diagnosis of submersion having taken place during life or after death, Dr. Bougier made a new study of the subject. From experiments and autopsies at the Morgue, he formulates the following conclusions: 1. The exterior aspect of the body is about the same in both cases—that is, when the body has been submerged before or after death; the appearance of moss on the body would be of some diagnostic value. 2. Water and foreign bodies penetrate into the air-passages and into the bronchial tubes of those submerged before, as well as of those immerged after death; but in the latter the foreign bodies do not go beyond the fifth or sixth divisions of the bronchial tubes, and the liquid is arrested at the bronchi of medium size by the column of compressed air; whereas, in the submerged during life, it penetrates down to the small bronchial tubes. 3. The epiglottis is vertical in the submerged; it is only half open in the corpses immerged. 4. Water penetrates in a pretty large quantity to the stomach of the former, but never to that of the latter; and in making a comparative analysis of the liquid found in the bronchial tubes, one might arrive at a certain diagnosis. 5. The same is the case with the middle ear. 6. The characteristic moss is found only in the submerged. 7. If the fluidity of the blood exists in certain cases of poisoning by opium, it is easy by the aid of the spectroscope, and by analysis, to form the diagnosis. 8. In putrefied corpses, all the signs have nearly disappeared, and the medical jurist can only draw conclusions by presumptions.

Picrotoxin in the Night-sweats of Phthisis.—In several cases in which atropine, quinine, and ergot had proved unsuccessful, Dr. Westbrook obtained excellent results with picrotoxin. It was given by hypodermic injection in dose of one-half to one milligramme ($\frac{1}{120}$ to $\frac{1}{60}$ grain), gradually increased to three milligrammes. It was also efficacious when given by the mouth.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE LIFE HISTORY OF THE CHOLERA MICROBE.

WE referred recently in these columns to the investigations of Dr. Ferrán into the morphology of the cholera microbe, and stated that he claimed to have seen this micro-organism under various strange and hitherto unsuspected forms. A commission of the Royal Academy of Medicine and Surgery of Barcelona, was appointed to examine into the methods pursued by this eminent naturalist, and the conclusions derived from his studies. This commission has now made its report, and has not only approved of the methods, but has fully sustained Dr. Ferrán in his views concerning the life history of this microbe. This report we find published in the *Gaceta Médica Catalana* of March 31, 1885.

If, according to Dr. Ferrán, the comma-bacillus be transplanted from the ordinary gelatine culture to a liquid medium, in the succeeding series of cultures the spiral form tends to disappear and to be replaced by long, somewhat wavy filaments. That this is not a strange form, introduced from without, is shown by the fact that, when retransplanted to a gelatine culture, the characteristic spirilla, S-shapes, and commas are reproduced. Examining a drop of liquefied gelatine taken from the apex of the cone in a test-tube culture, Dr. Ferrán found here and there a spirillum having a minute spherical body at one or the other extremity. This was rare in gelatine cultures, but of very frequent occurrence in liquid media. The body thus found increases in size until it exceeds that of a red blood-corpuscle. It is colorless and formed, of protoplasm, which, at first of uniform consistence, soon begins to contract and to collect at one or another portion of the sphere, leaving thus a cavity of irregular shape surrounded by a transparent hyaline envelope. The filament remains attached to the sphere at the point where the collection of protoplasm is found, and the protoplasm itself is soon formed by a process of segmentation into granular matter. Upon the filament, near its extremity, a second sphere is usually found which does not, however, attain the size of the first, and which Dr. Ferrán is inclined to regard as the pollen mass.

After the protoplasm has been converted into granules, the periplasma or hyaline envelope is ruptured and the granules are set free in the culture-fluid. It is probably at this time that they are fecundated by the pollen, though possibly the pollen mass penetrates into the sphere before its rupture. The granules set free in the fluid begin soon to increase in size, and assume one of two very different appearances. They either grow rapidly to an enormous size, presenting as smooth spherical bodies, or else they remain of smaller size and become roughened and bulbous-looking on their surface. The former are probably sterile, though they have not yet been sufficiently studied to determine exactly what they are. After a while, from one of the roughened spheres, "muriform bodies," a very long and minute filament shoots out like a jet of protoplasm. The part of this filament nearest the sphere is almost invisible, but the distal extremity soon acquires sufficient volume to enable it to be distinctly seen. Little by little this filament becomes wavy and then spiroidal, and finally develops into the unmistakable cholera spirillum. And thus the circle of existence of the so-called comma-bacillus is completed. In order to observe this mode of reproduction it is necessary to prevent the too rapid growth by scission, which is that most likely to occur in rich cultures and at elevated temperatures. We cannot now detail Dr. Ferrán's methods, but must content ourselves with this brief account of his conclusions.

This is certainly a novel morphological history of what we have learned to call the comma-bacillus, and it can hardly be accepted without further proof. Yet we must confess that there are many elements of probability in favor of Dr. Ferrán. In the first place, the reputation which this learned naturalist already has for scientific accuracy calls for at least respectful attention to what he advances, and forbids us to reject his theories until they have been disproven. Then the endorsement of the Royal Academy of Barcelona, and of other scientific bodies in Spain, would not be given lightly and without careful investigation. And, thirdly, we find corroborative testimony from Belgium, where Van Ermengem reports finding bodies in his cultures which are apparently identical with the muriform bodies of Ferrán.

Of course, a micro-organism presenting such a life history is not a bacillus. Dr. Ferrán has called it the peronospora barcinonæ after his native city, but we see no reason why, if his discoveries are verified, the name of peronospora Ferrani, already given to the microbe by a number of enthusiastic Spaniards, should not be accepted by scientific men of other countries as well.

THE HEALTH OF THE FRENCH TROOPS IN FORMOSA.

IT seems strange that so little care should be given to the commissary department of modern armies. It is little to be wondered at that the Crusaders should have undertaken their wars without much preparation for insuring their health after arriving in the Holy Land, but that the governments of modern Europe should send out soldiers to hot and unhealthful countries, without any thought as to how they are to be cared for when there, does appear incredible. Yet such would seem, in a measure at least, to have been the case with regard to the French soldiers in China. Several abstracts from the private letters of an officer stationed in Formosa are published in a recent number of *L' Union Médicale*, in which the condition of the troops in that island is shown to be most deplorable. Lodged in miserable Chinese cabins lying in the mud, half starved, insufficiently clad, and

overworked, the poor men sickened and died in frightful numbers. Of 130 men in the command of the writer, 72 were at one time lying in the straw huts, shaking with the fever, without physicians and without medicines. "Instead of sulphate of soda we were given sea-water, and instead of sulphate of quinine, kind words." Of 1,800 men in Ke Lung in October, between 800 and 900 were fit for duty on Christmas day; the other thousand were sick or dead. There was not only a lack of medicines and other necessities for the sick, but there was a short supply of provisions, and such food as could be had was hardly fit to eat. The results of such neglect are beginning now to be felt, for, as recent cablegrams have reported, the French have sustained a humiliating defeat, and one portion of their forces is even in danger of extermination. If, however, the present unsanitary condition of the invading army is allowed to continue, the Chinese need not risk their lives in an engagement, but may be content to keep out of the range of the French guns, while their powerful ally, disease, is thinning the ranks of their enemy.

THE EPIDEMIC AT PLYMOUTH.

It is a long time since the country has seen so extensive and fatal an epidemic of typhoid fever as that which has been affecting the town of Plymouth, Pa. Since April 17th, between 1,000 and 1,200 persons in a population of 8,000 have been attacked, with already about one hundred deaths. The disease, in most cases, is undoubtedly true enteric fever, but a large number appear also to have suffered only from civic, or marsh malaria.

The origin of the epidemic is satisfactorily accounted for by the local physicians, Drs. Murphy, Taylor, and Miner. The town of Plymouth is situated on a belt of alluvial soil and upon foot-hills which slope toward the Susquehanna River. There are, it is said, always some malarial diseases among the inhabitants. The water-supply comes from reservoirs, which are filled by a brook that drains into the Susquehanna. The town has no sewage system, and is filled with a mining population, of which the greater part is too poor or too ignorant to pay any attention to sanitary laws.

Last winter a person, while visiting Philadelphia, contracted typhoid fever. The disease appeared after his return to Plymouth, in March. While sick he occupied a house about forty feet from the banks of the brook, between the third and fourth reservoirs. The excreta were thrown upon the snow near the bank. When the snow melted, the infectious material was drained into the brook, and thence to the reservoir, from which it was distributed through the town. This view of the origin of the disease is corroborated by the fact that, in many instances, families which were supplied with well-water did not take the disease.

That the disease is, in most cases at least, typhoid fever, has been established by the testimony of the physicians, as well as by post-mortem examinations made by Dr. French and Dr. E. O. Shakespeare, of Philadelphia. The possibility of the introduction of the typhoid fever poison into a community by the pollution of the water-supply is well recognized. The bad sanitary condition of the town seems to have prepared a fertile soil in which the specific poison might develop.

THE BOSTON "MIND CURE."

We have before this noticed the interesting fact that most literary ladies of a slightly transcendental turn of mind are homœopathists. The faith of one of them became temporarily shaken a short time ago, and she turned to the "mind cure," which is now affecting Boston and vicinity with a kind of psychic storm. Miss Louisa M. Alcott forsook globules and faith in potentization for mesmerism, trust in prayer, and occult "passes." She describes her experience in an interesting way in the *Woman's Journal*:

"Writer's cramp and an overworked brain," she says, "were the ills I hoped to mitigate by the new cure, of which marvellous accounts were given me. With a very earnest desire to make a fair trial, I took about thirty treatments, finding it a very agreeable and interesting experience up to a certain point. No effect was felt except sleepiness for the first few times; then mesmeric sensations occasionally came, sunshine in the head, a sense of walking on the air, and slight trances, when it was impossible to stir for a few moments.

"Much cheerful conversation, the society of an agreeable person, and the hope that 'springs eternal in the human breast,' made these earlier weeks very pleasant. But when bodily pain was alleviated, and instinct warned that something was wrong, I began to question and doubt a theory which claimed to cure cancers, yet could not help a headache. I made myself as passive as a reasonable being can, hoping that since lunatics and children were helped, I also could be if I gave up trying to see, believe, or understand. But when thirty treatments left the arm no better and the head much worse, I dared lose no more time, and returned to the homœopathy and massage from which I had been lured by the hope of finding a short and easy way to undo in a month the overwork of twenty years.

"This is my experience, and many others who have made the same experiment tell the same story, while half the fabulous cases reported to me prove to be failures like my own when investigated.

"My opinion of the matter is that, being founded on a fact which no one denies, namely, the power of mind over body, there is truth in it and help if it is not overdone and more claimed for it than is due.

"Mesmerism, unconsciously used, perhaps, does much; curiosity, the love of the miraculous, the hope of health, and more than all, the yearning of weary spirits for divine support, lends this new craze its charm, and attracts the crowd of sufferers who fill the rooms and pockets of the persons who profess the healing gift."

Miss Alcott's analysis of the matter is, no doubt, a truthful one. So much so, that we should be glad to see her apply her analytical powers to Hahnemannism also. The "mind cure" is mesmerism over again, applied to practical therapeutic uses. The mind-curers are doing just what Mesmer did with his "magnetic fluid" at the beginning of this century; and what Mr. Braid and Dr. Elliotson did forty years ago. Mesmerism and "mind-cures" do effect some cures, but their influence in therapeutics is, on the whole, not a good one, especially as long as the methods are in the hands of the ignorant, quackish, and self-deluded. For every individual permanently helped, there are a dozen who are either not

helped or are positively injured. The educated physician, however, should know well the power that lies in these forms of therapeutics. Used by him judiciously some good may be obtained. The occasional revival of faith- and mesmeric-cures may, therefore, be of some value in enlarging the understanding of the physicians of the resources of therapeutics and the modes of action of remedies.

HOSPITAL EXAMINATIONS.

The season is upon us when the semi-annual changes are being made in the resident staffs of our various metropolitan hospitals. The candidates for the vacant positions are, almost without exception, drawn from the ranks of recent graduates of our three leading medical schools. As far as we know, the examinations are all conducted in a spirit of fairness and impartiality. Complaint has been made that students—in every way qualified—from institutions in other cities are either not allowed to compete, or at least are so discouraged in advance from so doing that they are practically thrown out of the race. Under these circumstances it is alleged that the universal competition announced is so but in name. In regard to this point, we think that something can be said on the other side. The positions in our hospitals are coveted for their clinical opportunities. The hope of enjoying them is doubtless the reason why so many of our liberally educated students come to New York to receive their medical instruction.

In regard to the examinations themselves, there are several features which might, we think, be changed with profit. In the first place, they should, in some cases, be held earlier in the spring, so that non-resident graduates intending to compete should not be put to the trouble and expense of remaining in the city for several weeks—simply waiting for the time of their trial to come. Again, more time should be spent in the examinations themselves, and a wider range of subjects should be gone into, else a mere attendant at lectures is given preference over the man of wider reading and more varied resources. This change could easily be made without verging at all outside the domain of practical medicine and surgery. Finally, the examinations should be of a more practical character. This, involves, of course, more labor on the part of the examiners, but an increased efficiency in hospital work would certainly result therefrom. The men simply "crammed" would be displaced by those more practically qualified. Now it is possible for a man with prodigious memorizing powers to pass a purely theoretical examination for a degree, and even hospital appointment, without ever having seen a single case of injury or disease. Judged by this standard alone, such men seem abler than that large contingent in every class not fluent of speech or even rapid of thought, but, who, when brought in contact with a clinical emergency, have a definite idea of what is the condition of affairs and what ought to be done to remedy it. These latter men suffer from the present mode of examination, while their more glibly-speaking competitors bear off the palm. Often men who have stood high on the prize-lists of our colleges have displayed a woeful lack of practical knowledge when called to meet the emergencies which arise every hour in our large hospitals.

There is a difference between practical questions and a practical examination, yet the former are the nearest approach to clinical work that can be reached apart from the bedside. This method is one certainly desirable to cultivate in all forms of examination and instruction. The higher ranks of the profession are to be recruited from our hospital internes, and we should start at the outset with the best possible material.

BLISTERS IN PNEUMONIA.

Several French physicians have been discussing the question of the utility of blisters in the treatment of acute lobar pneumonia and acute bronchial affections. M. Dauvergne, who opened the subject recently, takes ground against vesication, claiming that it not only does no good but may even cause harm. Dr. Dejean, of Nasbinals, writes to the *Bulletin Général de Thérapeutique*, in support of this view. He reports two cases which he had recently been called upon to treat. The patients were attacked with symptoms of pulmonary congestion and incipient pneumonia. Some member of the family applied blisters over the painful parts. Next day the disease was much worse, the congestion having greatly increased, causing severe dyspnœa and general distress. Both patients soon died. The cases, if they do not prove a point, illustrate one, viz., that the application of blisters in the early stages of pneumonia is not indicated, and may even be harmful. It is commonly taught that vesication in the later stage for the purpose of promoting absorption is advisable. While this practice has much clinical evidence in its support, it is, we believe, often carried too far. Extensive blistering is sometimes employed in the later stages of pneumonia, not so much to promote absorption as to arrest the progress of the disease and bring on the crisis, a thing which blisters will probably never do.

What is Dental Surgery?—We note that in nearly all of the States and in the District of Columbia laws are being enacted limiting the practice of "Dental Surgery" to a certain privileged class which is designated as above. Now if it is intended that physicians shall not treat any disease of the mouth unless they take out a degree from some dental "college" or from some medical school where there is "annually delivered a full course of lectures and instructions in dentistry or dental surgery," as the Kansas Dental Law has it, it is about time that medical men were looking to their interests. The above law, however, generously permits "physicians, surgeons, or others," to extract teeth! If the dental "profession" has any claim to consider itself a specialty in medicine, this course is calculated to exclude it utterly. What would be thought if ophthalmologists, otologists, or gynecologists were to secure legislative enactment to prevent their medical colleagues from practising in their field unless they adopted the "profession" of ophthalmology, otology, or gynecology, by taking out a "degree" in these respective branches? Such laws must be unconstitutional, or at least in conflict with the charters of medical schools, which are supposed to send out graduates empowered to treat any of the ills to which the flesh is heir.

News of the Week.

Bequests to Hospitals.—The late Mrs. Jane Holmes, of Pittsburg, Pa., bequeathed to the Allegheny General Hospital $5,000, and to the Home for Incurables sixteen acres of ground and $100,000.

A Medical Commissioner of Charities and Correction.—Mayor Grace has appointed Dr. Charles E. Simmons, of this city, to the vacancy on the Board of Commissioners of Charities and Corrections. Dr. Simmons is a gentleman of fine education and good medical standing. He graduated from Williams College, and subsequently completed his studies at Göttingen University. Then he returned to this city and in 1864 was graduated from the College of Physicians and Surgeons. He practised his profession in Troy for four years and then settled in this city, where he has been ever since. Dr. Simmons is an ardent Democrat, and has been an active political worker in some of the Presidential campaigns.

The Reporting of Contagious Diseases to the Health Department.—The number of cases of contagious diseases reported to the Health Department are so out of proportion to the deaths, that there is no longer doubt that physicians are becoming more and more neglectful in reporting them. The following is the table of deaths from contagious diseases for the months of November, 1884, December, 1884, January, 1885, February, 1885, and March, to the 14th.

Months.	Number of Deaths.	Cases Reported.	Cases Unreported.
November, 1884	325	137	188
December, 1884	372	166	206
January, 1885	347	165	182
February, 1885	312	139	173
March 14, 1885	146	54	92

This shows that, out of 1,502 deaths which occurred during that period, only 661 had been previously reported, considerably less than one-half.

The Board has accordingly passed the following resolution:

"*Resolved*, That the Sanitary Superintendent be directed to send to the Attorney for prosecution the name of every physician neglecting to comply with Section 131 of the Sanitary Code, which relates to the reporting by the physician of all cases of contagious disease which he has prescribed for, or attended for the first time, during any part of the preceding twenty-four hours."

Rodney G. D. Finch, died of phthisis, at Statesville, N. C., April 20, 1885, after an illness that confined him to his bed only for a few days. Dr. Finch was born February 24, 1858, at Shrewsbury, N. J. He studied medicine with Dr. James R. Wood, and at the University Medical College. He graduated in 1881, when he received the third prize, of $200, given by the faculty. Immediately after graduation he entered Charity Hospital and served for eighteen months. Upon leaving the hospital he opened an office in the city and became connected with the University Medical College. He was Attending Physician, Dispensary of the Church of the Holy Communion, and a member of the County Society. He was an earnest worker, and had built up a very good practice when his health began to fail and he had to leave the city.

American Medical Editors' Association.—At the annual meeting, held in New Orleans, Dr. H. O. Marcy, President, delivered the anniversary address, and the following were elected officers for the ensuing year: President—Dr. H. O. Walker, of the *Medical Age*, Detroit, Mich.; Vice-President—Dr. F. L. Sim, *Mississippi Valley Medical Monthly*; Secretary—Dr. F. E. Daniel, *Courier-Record of Medicine*, Texas.

Children's Hospital, Randall's Island.—Dr. Geo. B. Fowler has been appointed Visiting Physician to the Children's Hospital on Randall's Island.

The Late Dr. S. Teller.—Dr. S. Teller, died on the morning of March 13, 1885, of erysipelas contracted from a patient while in the discharge of his professional duties. He was born in Prague, on November 30, 1830. After finishing his preparatory studies at the Gymnasium of his native city, he went to Vienna. Dr. Teller received his diploma in 1858 and acted for a time as assistant at the great general hospital of Vienna. He then came to this country and was soon made House-Physician of the Mount Sinai Hospital. About fourteen years ago, Dr. Teller began to engage in private practice, in which he continued up to the time of his last illness. He was a member of a great many charitable organizations, as also of the County Medical Society, Academy of Medicine, Medico-Legal and Neurological Societies. Twelve years ago he assisted in the founding of the West Side German Dispensary, to which he gave much time and earnest labor. Like so many who have preceded him in death, he fell a sacrifice to his devotion to duty.

The Indiana State Medical Society held its annual meeting during the past week at Indianapolis.

Rendering Unto Cæsar.—Our alert and amiable contemporary, the Texas *Courier-Record*, accuses us of not giving it credit for advising the expectant and dietetic treatment of pin-swallowing. We are only too glad to correct any act of injustice, if such has been done. In The Medical Record of December 20, 1884, page 695, is a note by Dr. Smith, of Syracuse, N. Y., in which he reports a case of shawl-pin swallowing successfully treated by expectancy. It was to this that we believed the physician in York, Pa., referred.

No Law Regulating the Practice of Medicine in Texas Exists.—We say this in answer to some queries upon this subject.

College of Physicians and Surgeons, N. Y.—The annual commencement of the medical department of Columbia College took place May 12th. Dr. John C. Dalton, President of the College, conducted the exercises. After the conferring of degrees, the awards of prizes were made. The highest prize, of $500, was awarded to G. Woolsey, a son of ex-President Woolsey, of Yale College; the second prize, of $300, to H. B. Sweetzer, Jr., and the third prize, of $200, to B. L. Ten Eyck. An address to the graduating class, by the Rev. Dr. Charles H. Parkhurst, closed the exercises.

The Colorado State Medical Society meets at Denver on the third Tuesday in June.

The Atlanta Medical and Surgical Journal has been made the official journal of the Georgia State Medical Association.

The Weekly Medical Review.—Dr. Tilley, the Chicago editor of our esteemed contemporary, the *Weekly Medical Review*, having resigned, the St. Louis editor, Dr. Robert Luedeking, has assumed sole editorial charge.

The Medical Association of Georgia, at its annual meeting at Savannah, April 14th to 16th, elected the following officers: R. J. Nunn, Savannah, President; L. B. Alexander, Forsyth, First Vice-President; T. F. Walker, Cochran, Second Vice-President; Dr. James D. Cray, of Atlanta, Secretary. Augusta was selected as the next place of meeting.

The Syphilis Bacillus.—At a meeting of the Royal Society of Physicians of Vienna, April 17th, Drs. Fürth, Mannaberg, and Zeisse reported confirmations of Lustgarten's discovery of a bacillus of syphilis.

A Dublin Surgeon who displayed a black flag from his house on the occasion of the entry of the Prince and Princess into Dublin has been boycotted by his professional brethren.

Enlargement of the Boston City Hospital.—The City Government has appropriated $40,000 for the erection of an additional building in connection with the city hospital to be used for the isolation of contagious diseases.

Dr. J. W. Holland, of Louisville, Ky., has been elected Professor of Medical Chemistry in Jefferson Medical College.

The Annual Commencement of the University Medical College of Pennsylvania was held on May 1st, when 108 students were graduated.

The Carnegie Laboratory of Bellevue Hospital Medical College was formally opened to the profession on Thursday evening of this week. During the evening there was an exhibition of bacteria and the processes of their cultivation.

Yellow Fever Inoculation.—Dr. Domingos Freire has inoculated 1,109 persons with his protective "vaccine" from December 22, 1884, to March 22, 1885. No accidents followed, and in almost all cases there was a slight rise of temperature and some constitutional symptoms.

The Medical Association of the State of Alabama held its thirty-seventh annual session at Greenville, April 14th to 17th, Dr. B. W. Riggs, President, in the chair. There were over one hundred members present. The following officers for the ensuing year were elected: D. F. M. Peterson, of Greensboro, President; Dr. Star, of Wilcox County, and Dr. Richard M. Fletcher, of Madison County, Vice-Presidents. The Association will meet at Anniston next year.

The Fifty-Second Annual Meeting of the Tennessee State Medical Society was successfully held recently. Dr. T. L. Maddin, of Nashville, was elected President, and Memphis was chosen as the next place of meeting, the first Tuesday in April, 1886.

"The Sanitary Monitor" is the title of a new monthly journal published in Richmond, Va., and edited by Dr. J. F. Winn.

Reports of Societies.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

(By Telegraph to The Medical Record.)

Eighty-seventh Annual Session, held in Baltimore, Md., May 12, 13, 14, and 15, 1885.

First Day—Tuesday, May 12th.

The Medical and Chirurgical Faculty of the State of Maryland was convened in annual session in the Hall of the Athenæum Building, corner St. Paul and Saratoga Streets, Baltimore, at 12 M., May 12th, over one hundred members and delegates being present.

Dr. Thomas S. Latimer, President, called the meeting to order, with Drs. G. Lane Taneyhill and Robert J. Wilson as Secretaries.

The minutes of the previous annual and special meetings were read and adopted.

PRESIDENT'S ADDRESS—ORIGIN AND DIFFUSION OF CHOLERA.

The address began with a detailed account of the course and history of the pandemics of this disease which have prevailed since 1817. Indigenous and long known in India it first extended to Europe in that year. The fifth epidemic is now moving westward. The parasitic nature of the disease the author did not consider proven, since Koch had not succeeded in producing the disease by injecting the comma baccilli, and Lewis had demonstrated the presence of bacilli in the human system, under other circumstances, not distinguishable from the comma bacilli. Drinking-water was one, but not the only means of the communication of the disease. Soil-contamination favors its development; the low-lying sections of the city are most subject to the epidemic influence.

The speaker continued:

"There is little ground for doubting that either this or the ensuing year the North American continent, and probably our city, will be visited by this terrible disease, and it has been fully demonstrated that in spite of the highest attainable efficiency, quarantine is of but little value. We need scarcely hope to escape its invasion by land should we successfully shut it out from our harbor. What is best, then, is clearly to put our city in such condition as will present the most unfavorable condition for its development, and this, it should be clearly understood, cannot be done by the authorities alone. It can only be effectively done by the cheerful, hearty, and intelligent co-operation of all classes of citizens. Let every house be thoroughly cleaned, every privy emptied and disinfected, every cellar cleared of all rubbish, and as thoroughly dried as possible, freely and frequently ventilated and disinfected. Let the streets be frequently washed, and never swept without *thorough* sprinkling. I am aware that Koch advises that the streets should not be wet frequently, because humidity favors the development of bacilli; but, on the other hand, Pasteur says they should, because dryness favors the diffusion through the atmosphere of such germs as may be on the surface. This seems to be far more rational advice. But whichever may be right, the objection of Koch does not apply to the period preceding the appearance of cholera, that period when activity is of most avail. Merchants and residents in the low-lying sections of the city should especially charge themselves with the enforcement of these sanitary precautions. The sweepings from stores and warehouses should not be cast into the streets, but should be put in garbage boxes to be carted away. Captains of vessels of all kinds should, as far as possible, be required to carry all spoiled vegetables and other decomposable substances outside of quarantine limits. All market-men should be compelled to *put at once* and keep all refuse in some receptacle to be carried away with them, and should

not be allowed to throw it on the ground to be gathered up and removed after market hours. I have a number of times seen market-men emptying barrels and boxes of refuse into the gutters during heavy rains that it might be washed away into the sewers.

"This is at all times a most reprehensible practice, and at such a time as the present a criminal one. In my judgment no particular form of diet is necessary as a precautionary measure. Ripe fruits and vegetables of all kinds when fresh may be temperately used. Moderation in their use is all important.

"Finally, should cholera arrive in our city, all the precautionary measures heretofore mentioned are to be continued, and in addition, all water for drinking should be well boiled and subsequently kept in covered vessels. All food should be well cooked. As soon as a case of cholera occurs, it should be promptly reported to the Health Department, the patient isolated, and the household disinfected.

"Dr. Austin Flint, quoting from the report of Elisha Harris (*Medical News*, April 18, 1885), tells us that in the last epidemic in New York, in 363 houses where individuals or families were smitten with cholera, but which were promptly brought under sanitary control by disinfection and sanitary purification, the pestilence did not extend beyond the family in which the first case occurred. More extended experience is necessary to enable us to speak with any confidence of the hygienic value of sulphur fires in neighborhoods most liable to attack, but it is worthy of mention that in 1872 at Sonnepore sulphur fires were kept continuously burning at intervals of fifty yards during the progress of the fair, and that not a case of cholera occurred, although it had generally broken out at previous fairs, and that a similar practice at Dinapoor was attended with a like result. Whether the burning of sulphur contributed in any degree to the immunity had at these places cannot, of course, be determined. To avoid panic, it should be strongly impressed on the public mind that only in very exceptional cases have attendants or cholera patients suffered to any greater extent than the rest of the community, when care is taken to keep thoroughly clean the house, clothing, and persons, together with proper disinfection of all excreta, and the freest ventilation. Flight is more expensive, less effective, and not so creditable. In the face of a common danger every member of a community has a definite duty toward his neighbor."

The address was referred to the Committee on Publication, and, on motion of Dr. S. C. Chew, a committee of three was appointed to take into consideration that part relating to the threatened invasion of this city by cholera, and report to the faculty in what way its influence could best be exerted in the premises for the good of the community.

The Treasurer, Dr. W. F. A. Kemp, reported that there had been 5 deaths, 5 resignations, and 6 dropped for non-payment of dues, a total loss of 15 active and 1 honorary member. There had been added during the year 8 active and 1 honorary member. The receipts for the year had been $1,583.24, expenses $1,682.79, leaving a deficiency of $99.55. The assets, including the value of the library, were $9,840.

The Board of Examiners of the Western Shore, through Dr. Chew, Chairman, reported favorably upon the names of Drs. George J. Preston, William J. Jones, Samuel T. Earle, W. T. Councilman, and E. E. MacKenzie, candidates for membership.

The Library Committee, through Dr. I. E. Atkinson, Chairman, reported the total number of books in library as 4,170, 321 of these being duplicates; 151 had been added during the year, and 94 volumes of journals had been bound. No bound volumes had been bought, owing to lack of funds; a number had been donated. Sixty-four journals are now regularly received, besides Society Transactions, Hospital Reports, etc., as usual.

Dr. John R. Quinan, Chairman of Committee on Memoirs, read sketches of the lives of Drs. Riggin Buckler, John R. Ward, Andrew Hartman, George S. Kinneman, and J. J. Woodward, deceased during the year.

On motion, the meeting adjourned to meet again at 12 M. to-morrow.

Wednesday, May 13th—Second Day.

Mrs. E. P. W. Packard, of Chicago, a philanthropist, addressed the Society in advocacy of

legislation for the protection of the insane.

Her suggestions were referred to the Committee on Legislation.

annual oration.

The annual oration was then delivered by Professor H. Newell Martin, of the Johns Hopkins University, on

the physiological action of drugs.

The object of medical education is to fit the student to practise, to enable him to destroy his enemy—disease. The fundamental qualities necessary for the modern physician are the same as in ancient times, but laboratories of physiology, pathology, and experimental therapeutics have added to his knowledge and resources. The orator proposed to consider cure of disease rather than prevention. A chief object of such meetings as this is to take stock of the year's work, to consider the progress made, and its value. He could "imagine no topic of greater interest at this moment than intracranial surgery; the promise, the just expectation that in the near future the medical man may operate within the arachnoid cavity almost as he now does within the peritoneal, and with equal certainty of diagnosis, and equally reasonable faith of a successful issue!" He addressed them as one concerned rather with the theory than the practice of the medical arts, as one whose relation to our noble warfare is rather that of him who prepares cartridges in the arsenal than that of the soldier who handles the rifle and bayonet at the outposts. He could not forbear, however, to point out that this new branch of surgery, which promises so much benefit to our fellow-men, is in the main due to researches which in their origin had no direct connection with the problems of practical surgery.

Pharmacology, or investigation of the action of drugs in the healthy body, has in the last few years attained an importance, in relation to therapeutics, which is not yet fully realized. It can hardly be said to have existed until the present century. Among the Greeks medicines were considered mysterious, as possessing magical power, inherent or imparted by sorcery. *Pharmakos* meant alike a physician, sorcerer, poisoner. Something of this old notion still exists among the laity, and many otherwise intelligent people are gulled by the jargon of the supernatural virtues of infinitesimal doses raised to tremendous potency by the seventeenth trituration.

The discovery of useful remedies in former times was a matter of accident. By multiplied experience the list of medicines was slowly increased. According to Strabo, the Egyptians exposed those dangerously ill, that passers-by who had seen a similar case recover might advise treatment. By repeated empirical trials some remedies proved of use in certain diseases, and these formed the beginning of our materia medica. Later, the votive tables placed in the temples by grateful patients added to the list. In the Dark Ages the Arabs did something to advance pharmacology, the Europeans almost nothing. The empirical method of the ancients was good, as far as it went; what they had found good before they gave again, on the same principle that we now give quinine in intermittent fever.

In the Middle Ages this sound, if narrow, Hippocratic method gave way to all sorts of fanciful doctrines as to drugs, regardless of observation as to their effects, as, for example, the doctrine of "signatures" of Paracelsus, in

the sixteenth century. According to this, plants, etc., acquired virtues from the stars, and it was the duty of the physician to decipher the signatures or marks which indicated these virtues. This wide-spread doctrine may still be traced in the names of many familiar plants.

Pharmacopœias of the sixteenth, even of the eighteenth, century contain substances of the most repulsive character, or supposed to have virtues connected with fantastic notions as to the animals from which they were derived. While there was no serious study of facts, no experimental investigation; while tradition, not observation, ruled, pharmacology could not be born. Even after Sydenham had led the way back to the sounder Hippocratic methods, it had to wait till chemistry supplied pure drugs, and experimental physiology had taught us how to examine their action in the tissues. The first pharmacological research was made by Magendie on strychnia, and his investigations, which still constitute our guide in using this remedy, were detailed at length. It is almost incredible that, but sixty years ago, it had not been proven for a single medicine that it had a special affinity for, and specific action on, some one organ.

The orator next considered chloral, a remedy which we owe entirely to scientific research—an artificial product created by the chemist, and whose introduction was due to a knowledge of its chemical reactions outside the body. The theory on which it was employed—that it might give rise to chloroform within the body—has not been confirmed, but the value of the drug remains, and we owe our knowledge of it to scientific research; "to chemistry, which led Liebig to discover it and induced others to study its reactions; to physiology, which taught us that the blood was alkaline; to pharmacological research, which, by experiment on the lower animals, demonstrated its power, according to dose, to cause sleep, to abolish consciousness, to act as a valuable antidote in cases of strychnia poisoning; to these we owe its place among our most valued weapons in our fight against disease. Were it not for chemical research, there would not be one grain of chloral hydrate in the world to-day; were it not for physiological experiment, we should be ignorant of its value in the treatment of disease."

A further illustration of how a new remedy is discovered, and how many sciences co-operate to add to the physician's armament, was found in amyl nitrite, a remedy still not officinal, and now being born, as it were. The chemist discovered it, the physiologist and pharmacologist have experimented with it, and now the practising physician is testing it clinically. Whether the reasoning which led to its trial in angina be or be not based on sound physiology and pathology, the fact remains that by no mere chance, but by scientific reasoning, the drug was first tried in this terrible disease.

Numerous other examples might be cited of valuable additions to the materia medica due to pharmacological and physiological research. The story of the past, thoughtfully read, is the safest guide for the future, in which will be realized the results of the activity of modern chemistry, which is continually discovering new agents, not one in a hundred of which is being tested as to its physiological and therapeutic properties.

The Professor continued and spoke of the importance of laboratories for the study of the action of drugs on the living body. There is no such institution in the United States used *exclusively* for this purpose. He gave it as his opinion that pharmacology depends upon experiments on living animals. He thought such observations should be tried on the lower animals first, and explained that it is a great fallacy to suppose that the chief thing to be considered in vivisection is pain. Its object is to save life as well as to relieve pain in man. Men and women subject themselves and their children to pain in order to correct deformity or enhance beauty, which shows that in their judgment physical pain is not the worst thing in the world. We desire to increase our effectiveness as physicians; is not a practice which offers reasonable hope of doing this, though it involve the sacrifice of a hundred, nay a thousand animals, and some of them suffer pain, justifiable and right? When we consider the great activity of chemistry in discovering new compounds each year, the probable value of some of these therapeutically, and the diseases which now baffle our skill, we can appreciate the importance of not hindering scientific research.

The latter part of the address was devoted to a defence of vivisection, on account of the practice of which Professor Martin has been subjected to severe criticism, not only in this community but also in England; to which he has replied in a pamphlet.

The address was listened to by a large audience, about two hundred and fifty.

REPORT OF THE CHAIRMAN OF THE SECTION ON SURGERY.

Dr. Robert W. Johnson presented a brief review of the advances in surgery. Referring to the use of ether by the rectum, he said it was only to be preferred where operations were to be performed about the larynx, requiring the use of the actual cautery. Chloroform is no longer admissible as an anæsthetic, except in cases of obstetrics, and where ether is inadmissible. The man who, for personal convenience, exposes his patient to the greater risk of death by this means, should, if that patient dies, be held responsible. We are still at sea about surgical dressings. The spray has lost ground, but all are agreed as to the necessity of perfect cleanliness. Corrosive sublimate and iodoform offer great advantage, on account of cheapness and portability. Reference was made to Godlee's operation for removal of tumor from the brain. But the greatest triumphs were in abdominal surgery, Dr. Bull's case of laparotomy and suture of the intestine for gunshot wound being characterized as the great operation of the year.

The abdomen should be opened in case of perforation of intestine, hemorrhage, extravasation of fæces, and beginning peritonitis, just as in cases where internal strangulation has been positively diagnosticated, but only under full and complete Listerism; first, because without operation the patient is almost sure to die; second, the danger is far more than counterbalanced by the chances of recovery. He advocated the spray here, because most laparotomies for wounds are done in general hospitals, and are hence strongly liable to infection.

A supplementary report from this section, presented by Dr. W. B. Platt, F.R.C.S., entitled, "Three Months Surgery at Bay View Hospital," was read by title.

REPORTS FROM THE SECTION ON OBSTETRICS AND GYNECOLOGY.

Dr. John Morris presented the report on gynecology. He said a general tendency to conservatism in the treatment of the uterus had been a marked feature in the labors of the year, and quoted Allbutt's Gulstonian Lectures and Shotter, President of the London Obstetrical Society, who had but uttered the sentiments of the profession in England and America on the subject. The ablest medical men in general practice in the United States had for years struggled against the many striking gynecological innovations which had been introduced into practice, and it is to be hoped that at last their judgment will be approved, and a more conservative course be pursued, as far as the ailments of women are concerned. Reformation cannot come too soon in this department of medical art. Dr. Morris referred to a paper read by him in 1875, in which pessaries were very earnestly condemned. Those views, then considered heterodox, have been growing in favor. He quoted similar views recently expressed by Horatio R. Bigelow, of Washington. The only pessaries which he employed and approved of were of cotton. He spoke of the operation of trachelorrhaphy as entirely unnecessary, and referred to a case in which operation upon a lacerated cervix was followed by a sciatica, which lasted a year.

The Alexander Adams operation of shortening the round ligament was useless and unjustifiable. Extirpation of the uterus for cancer of the cervix is unjustifiable; in cancer of the body of the uterus it is of doubtful propriety. He thought the muriate of cocaine would prove valuable in gynecological practices.

Dr. L. Ernest Neale presented the report on obstetrics. He first discussed Dr. Braxton Hicks' combined version in the treatment of placenta prævia. The most favorable statistics of this operation in Berlin show one per cent. mortality under one skilled operator; ten per cent. mortality under promiscuous treatment. Among its advantages are prevention of hemorrhage and cervical laceration (very common, owing to the vascularity of the parts), and of atony, and the better prognosis for the child than under other methods.

Dr. Neale presented

AN OBSTETRICAL FORCEPS

which he had devised, which attracted much attention. He illustrated its advantages and use upon a Gudin and Pinard manikin. He remarked that Simpson's forceps is still the one most used abroad. It cannot, however, be used when the head is at the superior strait. He endorsed the views of Dr. Fordyce Barker as to Tarnier's instrument, which, notwithstanding its advantages, is not yet in general use. The objections offered to it are its unwieldiness and complexity, its liability to cause laceration of the soft parts. Dr. Neale's instrument combines the qualities of both Simpson's and Tarnier's (the two principal forceps of the day) in one. He did not claim entire originality for it, as the idea of the button-hole joints had been suggested to him while abroad. The following explains the instrument: 1. An unaltered Simpson; 2, the button-hole perforations, one behind each fenestrum, into which traction-rods are inserted and maintained thereby the button on the end of the rods; 3, a removable compression thumb-screw, which sinks into a groove made in the extremities of the handles of the forceps; 4, a cross-bar, hard-rubber handle for the traction-rods like Tarnier's, in which handle is concealed a movable rod to be used at option, so as to render the swivel-joint immovable. The instrument was made by Williams, of Baltimore, and will cost about $12.

Dr. Neale exhibited other instruments employed by the obstetricians. He also illustrated

SCHULTZ'S METHOD OF RESUSCITATING THE NEW-BORN CHILD

in cases of asphyxia. The child is held by the shoulders, the thumbs resting upon the thorax, the child's head toward the operator and its anterior surface to the front; it is then swung upward, so that its feet perform a revolution, and lie between the head and the operator's body, the trunk being then in a state of forced flexion. The original position is then resumed by a reverse movement, and the repetition of these movements constitutes the method. Dr. Neale regarded it as more effective than Marshall Hall's or Silvester's, and related a case in which resuscitation had been secured after ten minutes, the measures mentioned and all others having been tried in vain.

He then reported two cases in which

FIBROID TUMORS HAD BEEN EXPELLED POST PARTUM

from the uterus, and spoke of the rarity of such cases in obstetric works.

Dr. Neale concluded his very interesting paper by some remarks upon abdominal palpation in pregnancy, as recently developed by systematic study in France, illustrating his words upon the manikin.

The President announced as the committee upon that portion of his address relating to the threatened epidemic of cholera, Drs. S. C. Chew, Geo. H. Rohe, and Richard H. Thomas.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 7, 1885.

A. Jacobi, M.D., President, in the Chair.

THE PHYSICAL EXAMINATION OF WEAK CHESTS AND THE DIFFERENTIAL DIAGNOSIS OF THE SEVERAL FORMS OF EARLY PHTHISIS.

Dr. E. Darwin Hudson, Jr., read a paper on the above subject. [See The Medical Record, May 9, 1885.]

Dr. A. L. Loomis was invited to open the discussion, and said that he had been interested very much in the paper, for the reason that the writer had defined sharply the physical signs of early phthisis, and, while he might not agree with the author of the paper altogether, he could, in the main, endorse the views which he had expressed.

First, with reference to inspection. He thought that those who had examined chests for a long time realized more and more the importance of careful inspection before any further physical examination was made. It often occurred that the appearance of the chest almost compelled a diagnosis of phthisis. The slight deformities he did not regard as of very much importance; for, in examining over fifteen hundred healthy chests he had found only ten per cent. which were entirely symmetrical; but by inspection knowledge was obtained which could not be secured by any other method. At least it was sufficient to make one hesitate concerning a positive diagnosis.

The next point which had interested him was the remarks of the author of the paper regarding the different areas which were important in examining the chest. When he first began the study of physical exploration, he received the impression that the infraclavicular spaces were the most important for examination in determining the existence of the early stage of phthisis, and for some years he listened in those regions first, and with the greatest care, and on the sounds which he heard there he rested, to a very great extent, his diagnosis; but later on he found that the interscapular space referred to by Dr. Hudson was very much more important than the infraclavicular spaces, and he had very frequently found the physical signs of early phthisis in that region when they were not present in any other portion of the chest. In many instances phthisis will be far advanced before its physical signs can be detected distinctly in an infra-clavicular space, and perhaps during the first six months of the disease the physical signs will be confined to the interscapular space.

With regard to the axillary spaces, even when there was extensive consolidation of the central portion of the lung, and there were evidences of phthisical development in the interscapular space, he had yet to find a case in which he had been unable to detect changes in the respiratory murmur in the axillary space which indicated phthisical consolidation.

With regard to percussion, he would lay more stress upon its value than the paper seemed to indicate; but, as percussion was often performed it was of but little value. The sledge-hammer percussion, and percussion always in one direction, was of but little value. It had also seemed to him that several taps made with the mallet or finger, as was very frequently done, tended to confuse the examiner, whereas a single stroke, firm but light, often told more, perhaps, of the exact amount of infiltration than could be gained by auscultation, especially in the interscapular space.

With reference to whisper, he had found it far more important than the audible voice, especially in determining the changes in the pleura which gave rise to only slight physical signs, and which could be determined very accurately by the whisper.

Vesicular respiration varied so greatly in different individuals that it was necessary to have listened to them for a long time before one could recognize the slight changes which experienced auscultators claimed were present. The vesicular murmur which occurred after

the suspension of the inspiratory act, he was unable to hear. He had come to recognize as important in the early stage of phthisis three features of the vesicular murmur: first, its softness; second, its harshness; third, its interruption. First, that soft vesicular murmur heard in adult life, not heard in childhood, lost in old age, but present in the middle period of life, was very important. When there was loss of this soft, breezy character, and there was in place of it a harsh sound, there existed changes in the bronchi which were perhaps to be followed soon by hemorrhage, etc. It was not a prolonged expiration, necessarily, but that peculiar harsh sound which came on the one side and was not heard on the other. If to that there was added a slight waviness of the respiratory murmur, so well described and so much insisted upon by Pollock, of London, the group included the physical signs which were most important in the diagnosis of phthisis before there were evidences of consolidation, which were so easily recognized. But if there was feebleness of respiratory murmur, still harsh, there was reason to believe that pleuritic changes, which were probably tubercular in character, were present. Dr. Loomis thought he had been able, more than once, to recognize the presence of acute phthisis a number of weeks before the hemorrhage occurred which ushered it in, and by means of this peculiar harsh quality of the inspiratory murmur.

Dr. R. C. M. Page said that the author of the paper and Dr. Loomis had left but little to be added, yet he would like to make a few remarks concerning myoidema. He fully agreed with the author of the paper, that myoidema was frequently present, coincident it might be, in pulmonary phthisis. Attention was directed to this condition first in 1830, by Stokes and Graves, who stated that it was more perceptible in the early than in the later stage of phthisis. This was just the reverse of Dr. Page's observation, and in one hundred cases or more, examined during the last winter, he had found that as emaciation increased the sign became much more perceptible. Mr. Lawson Tait, to whom we owed the name, had stated that it was more marked on the affected side, but Dr. Page had found this not to be the constant rule; but it was usually on the side on which emaciation was most marked. He believed that it was due to muscular contractility, and that it existed in all cases of pulmonary phthisis. He thought that it was present in some cases in which there were no other signs of phthisis, and referred to a patient in whom this sign was well developed, and in whom there were no physical signs of phthisis, but who had persistent elevation of temperature, a hacking cough, and a pulse of ninety-five.

Dr. E. G. Janeway said, with reference to myoidema, that he had studied it sufficiently to convince him of its unreliability as a physical sign of phthisis, inasmuch as it could be developed over muscles in different regions of the body, perhaps over the deltoid and biceps better than over the pectoralis major.

Concerning the physical signs of phthisis in its very early stage, the most any of us could do was to say that certain signs denoted certain conditions of the lung, and indicated limited condensation, consolidation, localized bronchitis, etc.; but the most important point was to determine the significance of such condensation, consolidation, or local bronchitis.

The important points, then, were, first, to prove the existence of pulmonary consolidation, or condensation, or localized bronchitis; and second, to determine the significance of such conditions if present. The chances for error were numerous, and would continue to arise. Hence, all the physical signs had their value, and the examiner could not dispense with any one of them.

There was a method of percussion which he thought had special value; that is, in all cases of doubt employ percussion *at the beginning and at the end of a full inspiration*, in both the supraclavicular and the supraspinous regions.

He also laid special stress upon the signs of irritation of the bronchi, and regarded as of special value the râles heard in the small bronchi and limited to the supra-scapular and supraclavicular fossæ, especially when brought out by coughing, and associated with a general condition of ill-health. The fine subcrepitant râles in these regions, especially if associated with the general condition mentioned and with cough, were especially important physical signs.

It was also important to determine whether or not the pulmonary consolidation or condensation was persistent; for pneumonias developed at the apex of the lung and ultimately cleared up without being followed by phthisis.

Dr. Janeway thought that the microscope should now be regarded as one of the aids in physical diagnosis, and that the presence and number of bacilli were a great aid in establishing a diagnosis of the kind of early phthisis. Of course, we might be obliged to wait for a considerable period to obtain sputum for examination, and yet during this time there were evidences of local bronchitis at the apex of the lung, without decided evidence of pulmonary consolidation. In such cases the sputum might not occur, or it might be swallowed, and considerable time might elapse before it could be secured for examination. In other cases, however, the microscopic examination of the sputum was exceedingly valuable, with the limitations that it was correctly made, and by proper methods—not by quick methods, such as were liable to give rise to the formation of crystals which have been confused with bacilli, and which have not distinguished the bacilli of the mouth from the tubercle bacilli. With proper restrictions, however, the presence of bacilli became of considerable value as a diagnostic sign, and he regarded it as one which should be employed. But it seemed to him that there were cases in which the physical signs could not be interpreted aright without strict inquiry into the history of the patient; for, there might be evidence of old pulmonary disease which was not tubercular in character.

Dr. Hudson, in closing, said that he essentially agreed with those who had participated in the discussion, but wished to say that he did not hope to cover the entire subject in a single paper, and therefore had not alluded to some of the points which had been mentioned by the gentlemen who had spoken.

By the term myoidema he did not mean muscle reflex at all, but simply a cutaneous reflex—as had been well described by one writer—a cutaneous intumescence, showing itself especially over the cartilages in the shape of little cutaneous conoidal elevations which arose after slight taps with the ends of the fingers, and remained from one to four seconds, and which had been described by Finlayson, and corroborated by Gairdner, as a cutaneous reflex. The question of the examination of the sputum for bacilli he had purposely omitted, because, thus far, the exact relation which existed between phthisis and the presence of these micro-organisms had not been established.

Dr. Janeway said that he examined carefully the photographs passed by Dr. Hudson, in order to make sure that he spoke of the same condition under the ordinary term myoidema; and he also thought that Dr. Hudson would admit that fibres of the pectoralis major muscle ran over the costal cartilages.

Dr. H. G. Piffard demonstrated the action of

THE FOOT-BELLOWS USED BY DENTISTS

in working the blow-pipe, and showed how it could be attached with special advantage to the ordinary spray apparatus and the Paquelin cautery.

The Academy then adjourned.

Tincture of Benzoin.—Dr. Kebbel recommends the inhalation of tincture of benzoin at ordinary temperatures, in the treatment of nasal catarrh.

AMERICAN MEDICAL ASSOCIATION.

Thirty-sixth Annual Session, held at New Orleans, La., April 28, 29, and 30, and May 1, 1885.

(Continued from page 526.)

[The following report is an elaboration of that sent by telegraph, and contains abstracts of such of the papers as have been referred to only by title.—Ed.]

SECTION ON SURGERY.

Dr. John B. Roberts, of Philadelphia, read a paper on

FALSE DOCTRINES IN THE TREATMENT OF FRACTURES.

He thought that the employment of the primary bandage under the splint was often unnecessary and sometimes did harm. The ensheathing callus was not so essential as usually claimed, if perfect apposition be secured and maintained. When fracture occurred near to, or involving the joint, early passive motion was not only of no avail in preventing anchylosis, but might even aggravate the condition by setting up inflammatory action. In fractures not involving the joint, passive motion was unnecessary before the end of the third or fourth week. With regard to splints, he said that they were usually left on too long. In fractures of the forearm or leg he thought ten or twelve days long enough. In fractures of the cranium thorough exploration was less dangerous than neglect of the same. In fractures of the nose it was impossible to keep the arch in position with the usual adhesive plaster-dressing, and transfixion with pins was the better way. The axillary pad was useless in the treatment of fractured clavicle, as it was only necessary to fix the posterior angle of the scapula. In fracture of the surgical neck of the humerus the author dispensed with the internal angular splint, and in that at or near the elbow he preferred to place the arm in a straight splint. The interosseous pad in fractures of the forearm seldom accomplished what was claimed for it.

Measurement of the lower extremities was of much less diagnostic value than was generally supposed, as there are always normal differences between the two sides.

In the discussion of this paper, Dr. Peck, of Iowa, said that his plan of treatment in fractures of the elbow was simply to lay the arm on a pillow and make passive motion every day.

Dr. Quimby, of New Jersey, was in the habit of commencing passive motion as soon as the inflammation had sufficiently subsided, and did not think it a good plan to wait three or four weeks. He agreed with the author that the interosseous pad was, to a great extent, useless.

Dr. Budd, of Missouri, thought that Dr. Peck was fortunate in obtaining good results with the treatment he advocated, for if anything was calculated to cause displacement of the fragments in fracture at the elbow it was motion of the joint. The arm should be kept quiet until inflammation had subsided. In fracture of the surgical neck of the humerus the arm should not be carried forward, as the author of the paper had advised, but should be maintained at the side, as in this position the muscles were not put upon the stretch. He thought that in fractures of the forearm splints should be kept on longer than ten or twelve days.

Dr. Murphy, of Minnesota, thought there was a great deal of humbug about splints. No two cases were alike, and consequently could not be treated by any inflexible rule.

Dr. Bird, of Illinois, had frequently treated compound fractures without splints, using simply an elastic bandage.

Dr. Cook, of Illinois, had recently treated a case of Colles' fracture without the pistol splint and had obtained a good result.

Dr. Elliott, of Georgia, said that the primary bandage would not produce bad results, if a plaster-of-Paris bandage were applied. And he regarded this as one of the best methods of treatment.

Dr. Francis V. White, of New York, also spoke favorably of plaster-of-Paris.

Dr. W. P. Verity, of Illinois, then read a paper entitled

THE TREATMENT OF COMPOUND FRACTURES BY WIRING AND DRAINAGE.

When a case of compound comminuted fracture came under his care, he said, the first thing he did after the surrounding parts were shaved and cleaned, was to remove all loose fragments which were liable to act as irritants, then trimming off the sharp edges if necessary, the ends of the bone were wired together. Free drainage was provided for by large tubes from the most dependent portion, and the whole extremity was then covered with a thick antiseptic dressing and encased in a plaster cast, which is to be removed at each dressing. He claims the following advantages for this method of treatment:

1. All points of bone and injured tissue-fragments likely to act as irritants are removed.

2. It is obvious that, as a rule, there can be no shortening.

3. No extension is needed, and thus the necessity of complicated apparatus, which too often interferes with proper antiseptic dressings, is done away with.

4. Proper retention of the fragments in place is presumably secured, thus avoiding any possible danger of the fragments overriding and irritating the soft tissues.

5. The bones unite more quickly for reasons which will be obvious when the principles which underlie all procedures to secure union of ununited fractures are recollected.

6. Drainage, besides its other advantages, prevents extension of the inflammation.

These points were well illustrated with a report of eight cases, accompanied by drawings, representing the pathological and fever condition of each case.

SECTION ON OBSTETRICS.

Dr. W. W. Potter, of Buffalo, reported a case of

PARAMETRIC ABSCESS.

The patient, a married lady, twenty-eight years of age, who had borne three children, was complaining for about a week of pain in the right inguinal region. There was nausea, occasionally vomiting, the temperature was elevated, and finally a severe chill occurred. She was examined at this time, and a pelvic abscess was found posterior to the uterus. This was evacuated, and the cavity at first washed out with solutions of carbolic acid, but no improvement following, iodoform was used with the best results.

The writer asked special attention to the following points: The rapid formation of the abscess; the extent of the same; the change for the better following the use of iodoform in the cavity. The expectant treatment, he said, was the treatment of yesterday; evacuation that of to-day. Given a case of pelvic abscess, confirmed in our diagnosis, we cannot hold back the operation one single moment without greatly endangering the life of the patient. We should first evacuate the cavity, then cleanse, and arrange for thorough drainage.

The next paper was one by Dr. Fenger, of Chicago, on

CHRONIC PERI-UTERINE ABSCESS: ITS TREATMENT BY LAPAROTOMY.

When an abscess is deeply situated behind the uterus laparotomy is very frequently required. The abdominal incision is to be made by preference with the thermo-cautery in order to avoid hemorrhage. Before puncturing the abscess it is well to introduce a large sponge,

which may be soaked in a solution of sulphate of copper, in order to absorb the blood or pus which first appears. We cannot always find a fluctuating point on the tumor, and it is sometimes necessary to introduce the needle several times before finding pus. The question of drainage-tubes in operations of this sort is an open one. Antiseptic precautions should always be taken. The writer preferred iodoform, but employed boric acid for injection. He did not regard a counter-opening into the vagina as at all essential in most cases.

Dr. George J. Englemann, of St. Louis, agreed perfectly with the author in regard to active interference in these cases, and believed that much harm might result from temporizing with iodine and the like. When the pus is inspissated, a diagnosis by bimanual palpation is exceedingly difficult.

Dr. Gordon, of Maine, thought prophylaxis the most important thing in pelvic abscess. In more than half of the cases which had come under his observation, he believed that the abscess was caused by the treatment which the patient had undergone. He was becoming more and more timid about introducing sounds into the uterus, as he believed them productive of much evil.

Dr. J. C. Reeves, of Ohio, reported a number of cases of pelvic abscess. He did not think young physicians were so much to blame for temporizing, as patients were mortally afraid of the knife, and would not only refuse to listen to any suggestion of that sort, but would also in all probability seek for other medical advisers.

Dr. W. A. Jaggard, of Illinois, mentioned the plan, as set forth by Dr. Byford in a recent paper, to dilate the anus and drain the abscess through the rectum.

Dr. G. J. Englemann, of Missouri, then read a paper on

THE IMPROVED TECHNIQUE IN GYNECOLOGICAL OPERATIONS, MAJOR AND MINOR.

His mode of operating was entirely different from that of American surgeons, and was more nearly like the European, although it differed from the latter in some original points. He claimed for his plan asepsis, simplicity, and rapidity, which he regarded as great desiderata. He described the method briefly as one in which all operations on the vaginal tract are made under the hot antiseptic douche. He used no sponges whatever, and had not done so for years. The patient is placed on the table on her back, in the lithotomy position, with oilcloth under her, and a tub to catch the drippings. The operator wears a large oilcloth apron to protect him from the water. Four assistants are necessary, two for the legs, one for the chloroform, and one for the douche. The large number of assistants required he considered to be a disadvantage. The purposes of the hot douche are perfect antisepsis and keeping the surfaces clean, pure, and exposed to view. The use of the knife is not interfered with. The hot douche acts as a hæmostatic, and renders the adjacent parts anæmic. The water should be kept at a temperature of 115° to 125° F.; for the sake of antisepsis he used either a 1 to 1,000 or 1 to 2,000 bichloride solution, or a one or two per cent. solution of carbolic acid. The supply-can for the water is to be placed two or three feet above the surface of the operating table, and the pipe is provided with a small nozzle. The water must strike from above and strike the bleeding part exactly. The hand of the assistant holding the speculum is a guide for the temperature of the water. This plan had been the ideal of the writer for seven years, and when three years ago he saw it carried out by European operators, he immediately decided to use it in all his cases.

The speaker then presented a speculum which was one of Simon's later ones, quite large and broad. On insertion it widens the vagina and draws the uterus down, simply by pressure on the perineum. The principal advantages of the instrument are a concave extremity, shortness, and breadth. After faithfully trying various kinds of sutures he concluded that all sutures are equally good if aseptic. He recommended asepsis in all major and minor operations, together with careful attention to details.

Dr. T. M. Healy, of Maryland, read a paper on

A NEW SPECULUM AND VAGINAL IRRIGATOR.

The object of the speculum which he presented to the Section was to do away with the services of an assistant, often so difficult to obtain in country practice. The holder was applied by a pad to the sacro-coccygeal junction, and at two other joints on the crests of the ilium. The patient could be placed either in the Sims or the dorsal position, and the instrument answered equally as well. The application of the instrument was demonstrated on the living subject.

Dr. E. G. Zinke, of Cincinnati, read an exhaustive paper entitled,

EMMET'S OPERATION—WHEN SHALL IT AND WHEN SHALL IT NOT BE PERFORMED?

In order to arrive at the most satisfactory possible conclusions, the writer had addressed a letter containing twelve questions, covering the entire subject, to twenty-five gynecologists of this country and Europe. From their answers, from the latest literature of the subject, and from his personal experience, embracing in all a record of 4,945 cases, the writer had tabulated the following conclusions: 1. The operation has been performed unnecessarily for symptoms similar to but other than those arising from lacerations of the cervix. Further, it has been done imperfectly, even without preliminary treatment, in many more; and the failure to give relief, as reported by several, is due to these two causes. 2. From our present knowledge we cannot, at this time, arrive at any definite conclusion, from the fact that many of the so-called consequences of lacerations of the cervix uteri are not settled beyond doubt. 3. Every one engaged in this department should carefully select his cases, and try every known means to give relief before resource is had to an operation. 4. The operation should never be performed *eo ipso* in cases of simple fissures or lacerations of the first and second degree. 5. In cases of eversion and disease of the cervical or corporeal cavity, or both, although attended by hyperplasia and displacement, it has been observed that all the symptoms abated, the parts returned to their natural condition, and no laceration was discoverable after alleviative measures had been instituted. 6. There are some cases of extensive lacerations of the cervix that seldom give rise to any inconvenience, and, therefore, an operation should be deferred until symptoms arise that will call for its performance. 7. The operation, although indicated, should never be performed until, by preparatory treatment, the parts have been brought into a healthy condition. 8. Near, and during, the climacteric period the operation should be postponed as long as possible, and the patient not exposed to any risks, since in many cases all the symptoms subside under proper treatment, and, because of senile involution, never return. 9. The operation is justifiable in cases of lacerations of the third and fourth degree, without complications, if there is a history of malignant disease in the family. 10. The operation may be performed with perfect propriety in young women, as a preventive, if the laceration is bilateral and extends up to the cervico-vaginal junction, or beyond it, even though there are no pathological changes; indeed, it seems to be the duty of every one who observes a lesion to that extent to urge the operation. 11. The operation is justifiable in any degree of laceration, and in rare instances even in fissures, when there exists cicatricial tissues, productive of reflex disturbances, annoying in character, and not tractable to any other treatment. 12. The operation is absolutely indicated in all extensive lacerations of the os, in which the cervix is everted, its mucous membrane and Nabothian follicles diseased, and especially if

there be granular or cystic degeneration present, provided the parts have first been restored to a healthy condition by palliative treatment.

Dr. Harvey, of Indiana, by request of the President, opened the discussion. He thought in many instances slight lacerations were more painful than large ones, as the latter become everted and cicatrized, and do not cause much pain. Small lacerations become converted into fissures, and are then very painful and tender. These small fissures he thought could be well compared to fissures of the anus in sensitiveness. These he thought, contrary to Dr. Zinke, should be operated upon; cauterization improves for a time, but by the end of three months we have the same conditions over again. In every one of those slight fissures he found, on anæsthetizing the patient and separating the parts, that the fissure was much more extensive than had been supposed.

Dr. Wathin, of Louisville, said Dr. Zinke might have included in his most elaborate paper the fact that it is sometimes necessary to operate immediately. A very small laceration may cause a variety of troubles local and general, which will at last require an operation. We should remember that every case is an individuality. He thought an operation is contra-indicated as long as the case improves under local treatment. Frequent recurrence after cure, sterility, or abortions, may be indications for operation.

Dr. S. C. Gordon, of Maine, said that Dr. Emmet states in his work that he has never seen a case of epithelioma of the cervix without an accompanying laceration. The profession generally admit that malignant disease is not necessarily hereditary. Therefore the speaker thought every case of laceration should be operated upon. He had operated over two hundred and twenty-five times, and did not believe in so much preparatory treatment.

Dr. King, of St. Louis, confirmed Dr. Harvey's remarks concerning small lacerations. He believed them to be more liable to develop epithelioma than the larger ones. All parts subject to much irritation are favorite seats of cancer, as, for example, the lips, tongue, cardiac and pyloric orifices of the stomach, cæcum, anus, and cervix. The speaker thought that Dr. Emmet was very inconsistent in saying that there is never an epithelioma without a laceration, and then advising against operation in all cases.

Dr. Carson, of Detroit, made the criticism that some gentlemen, in the discussion, had spoken of a woman as being well when she had a lacerated cervix. A woman, he said, who has a laceration, be it ever so small, is not well. He would operate in all cases. Had a man an ulcer or fissure of the leg, be it ever so small, he would have it promptly attended to, knowing what there was to fear.

Dr. Aldrich, of Pennsylvania, recommended operation in every case. He had seen mere scratches of the cervix cause great trouble.

Dr. Hale, of Illinois, said that he was more conservative, and did not agree with some of the speakers who maintained that all cases should be operated upon. It is, however, not always the apparently trivial laceration which should be operated upon. Sometimes quite large lacerations cause little trouble, and *vice versa*.

Dr. Healy, of Maryland, said that trivial lacerations do not "skin over" with new mucous membrane, as had been affirmed by some of the preceding speakers.

Dr. Lewis, of New Orleans, had once thought that every laceration should be sewed up; now, with larger experience, he operated much less frequently. He thought it not improbable that lacerations occur in every woman who has borne a child.

Dr. Marcy, of Boston, was glad to hear from gentlemen from all parts of this country that they were able to readily diagnose laceration of the cervix. Not so much could be said of our "masters" across the water. He said that he was more conservative regarding operating now than five years ago.

Dr. Reid, of Ohio, said he had seen hundreds of women who had had children, and no laceration of the cervix. If she had no constitutional or local symptoms, he asked, how could it be known that she had a laceration? She does not know it, the physician does not know it without an examination, which is uncalled for, and therefore wrong. He hoped the gentlemen did not go about the land examining every woman who had a child to see if she had also a laceration of the cervix.

Dr. W. W. Potter, of Buffalo, suggested to Dr. Reid that we sometimes legitimately discovered a laceration in the lying-in chamber.

Dr. Battey, of Rome, Ga., said, "The well need not a physician, but they that are sick." Much less did the well need a surgeon. He did not operate if the patient was doing well.

Dr. Sutton, of Pittsburg, closed the discussion. He said the point in dispute seemed to be, Should the operation be performed in every case or not? He had done the operation a number of times, simply to relieve the woman's mind. Patients were told they have a laceration, and were sent to him. He was obliged to operate for that laceration, or the woman would not be satisfied, and consequently not relieved. He did not believe that laceration of the cervix was always coexistent with cancer. While in Berlin, he had seen three cases of epithelioma of the cervix in young nulliparæ.

Dr. S. C. Gordon, of Portland, Me., read a paper entitled,

Reasons for and Results of Some Cases of Tait's Operation.

He had heard Sir Spencer Wells say, during a discussion on Koeberle's paper at Copenhagen last summer, that in no case should the ovaries and tubes be removed unless it can be demonstrated by the touch that these organs are diseased. But he challenged this statement, and gave a detailed account of seven cases of operation in which the functional disturbances and nervous symptoms were the principal guides in making his diagnosis, and in each case an examination of the specimens removed most abundantly confirmed the diagnosis. In several of these cases he showed that it was absolutely impossible to demonstrate by the touch the existence of the lesions found, and which were unquestionably the cause of the disturbances for which the operation was performed. The important lesions found were cystic and calcareous degeneration of the ovaries, not materially enlarging them, and closure of the tubes complicated with very small cysts of the same. In no case was there excessive enlargement of either, at least such as would be diagnostic.

He claimed that in these cases the nervous symptoms were due to this peculiar condition, which might never materially change.

The results of the operations were eminently satisfactory, in several cases producing absolute relief to symptoms (and this in the worst cases of suffering), while in others a gradual amelioration was taking place. He believed time was an important element in perfect recovery.

In all cases we should give the patient a fair and faithful trial of cure by all the well-known means, of rest, massage, local and general treatment, before resorting to the operation. Dr. Gordon did not use so-called antiseptics in any of these operations, hot water in abundance having sufficed in this as in other cases of surgery.

Dr. Battey, of Georgia, stated that he was well aware that his operation was considered by many to have a very limited field. Sir Spencer Wells in his extensive practice had used his operation but twice, and Dr. Mathews Duncan but once. Both of these gentlemen were warm friends of his, and would do the operation if they thought it best. Dr. Duncan said to him years ago that he had no use for his operation. Dr. Gordon's results are the usual results whether the tubes are re-

moved or not. Patients frequently have recurrences of pain in one year from the operation, having previously felt quite well. The patients should be told that they must be satisfied if they are entirely and permanently relieved in one, two, or three years.

THE FIRST FRENCH SURGICAL CONGRESS.

Held in Paris, April 6, 7, 8, 9, 10, and 11, 1885.

(Special Report for THE MEDICAL RECORD.)

MONDAY, APRIL 6TH—FIRST DAY.

PROFESSOR U. TRÉLAT, PRESIDENT, IN THE CHAIR.

THE Congress met in preparatory session on the morning of April 6th, and proceeded to the

ELECTION OF OFFICERS.

The following were chosen unanimously: President, M. U. Trélat; Vice-President, M. Ollier; Honorary Presidents, MM. Verneuil, Tilanus, Socin, Koeberlé, A. Guérin, Rochard, Gross, E. Boeckel, and Baron Larrey; Secretaries, MM. Petit, Prengrueber, Picqué, and Coudray; Assistant Secretaries, MM. Bazy, Castex, Julien, Poirier, Poullet, and Redard.

On the afternoon of the same day the inaugural session was held in the amphitheatre of the École de Médecine. The first thing in order was

THE ADDRESS OF THE PRESIDENT.

The speaker began with a recital of the history of the origin of the Congress and of the labors of the Committee on Organization. It was to Dr. Demons, of Bordeaux, that the Congress owed its existence, as he had proposed its formation, in a letter addressed to the Surgical Society. It was hoped that the Congress would serve as a rallying-point for the surgeons of France, where they might meet to compare views, and to become acquainted with each other, and that thus the cause, not only of science, but of good fellowship, might be promoted. The speaker then referred briefly to the

TWO GREAT SURGICAL DISCOVERIES OF THE PRESENT CENTURY,

anæsthesia and antisepsis, giving credit to the latter to Pasteur, Lister, and Alphonse Guérin. In concluding, he said that though this was called a French Congress, science knows no country, and he was rejoiced to see present, and to welcome as members, colleagues from America, Italy, Switzerland, Belgium, Holland, Poland, and Russia. He hoped that these foreign members would find their visit so pleasant and so profitable that they would repeat it each succeeding year.

The scientific work was begun by M. GROSS, of Nancy, who read a communication on

POSTERIOR TARSOTOMY IN INVETERATE CLUB-FOOT.

After having had an extensive and unsatisfactory experience with the various methods of treatment of inveterate talipes, he had adopted that of E. Boeckel, but had modified it by resecting the anterior extremity of the os calcis as well as the astragalus. His conclusions were that tarsotomy, with extirpation of the astragalus and resection of the head of the calcaneum, should be the treatment by preference of inveterate club-foot. It restores the foot to its normal shape, permits easy and graceful locomotion, and is free from the danger of relapses.

M. OLLIER then read a paper on

TOTAL RESECTION OF THE TARSUS, OR ANTERIOR TARSOTOMY, IN OSTEO-ARTHRITIS.

The author had formerly favored partial resections, but now, with a wider experience, he invariably resorted to the complete tarsectomy. The operation should be performed, however, only in adolescents, where it gave the best results. The form of the foot was preserved after cicatrization, and even the arch was reformed. A contra-indication to the operation was found, of course, in the co-existence of general tubercular infection.

M. PANAS related a case of

EXOSTOSIS OF THE FRONTAL SINUS.

upon which he had operated with fatal result. He was thus led to study the question, from a statistical point of view, more thoroughly than he had previously done, and had come to the conclusion that operations, whether partial or complete, for the removal of exostoses of the frontal sinus were attended with a fatal result more frequently than the authors of standard treatises seemed to suppose. He thought it preferable, when the tumor encroached upon the orbit so as to threaten destruction of the eye, to proceed at once to enucleation, as being the safer procedure, since the sight would be inevitably destroyed in either case.

M. DEMONS followed with a paper on the relative merits of

OSTEOTOMY AND OSTEOCLASIS IN THE TREATMENT OF KNOCK-KNEE OF ADOLESCENTS.

The author expressed his preference for osteoclasis as being the safer procedure and equally efficacious.

TUESDAY, APRIL 7TH—SECOND DAY.

M. OLLIER, VICE-PRESIDENT, IN THE CHAIR.

M. ABADIE read an elaborate paper on the respective influence of

MICROBES AND DIATHESES

upon the complications following traumatic or surgical wounds. He believed that diathesis was a secondary factor, certainly much less important than microbial infection. He instanced cataract operations as showing the very slight prejudicial influence exerted by diatheses. It was the same with larger wounds, untoward complications of which were to be traced to the influence of micro-organisms rather than to the pre-existence of any special diathesis. In conclusion the author insisted upon surgical cleanliness and the observance of antiseptic precautions.

M. SOCIN, of Basle, recounted the results of some recent investigations into the

PATHOGENESIS OF SUPPURATION,

undertaken under his direction by M. Garré, his laboratory assistant. He had found the yellow and the white micrococci, described by Rosenbach and Kräuse, in the pus of osteo-myelitis, but had been unable to reproduce these organisms by inoculation. The same parasites were also found in the pus of boils and phlegmonous abscesses, and they could not, therefore, be regarded as the specific agents in the production of osteo-myelitis. The identity of the various kinds of microbes was shown by a personal experience of M. Garré, who nearly lost his life from the effects of an immense carbuncle of the arm caused by inoculation with the microbe of osteo-myelitis.

M. VERNEUIL remarked that the results of these experiments were perfectly in accord with the clinical facts recorded by M. Debove in

ORANGE-COLORED SUPPURATION,

facts which he had had abundant opportunity of verifying during the siege of Paris and the reign of the Commune. Orange-colored pus was regarded as of evil prognostic import.

M. OLLIER recalled the fact that Rodet had succeeded in producing all the different varieties of epiphyseal osteitis by inoculation with the microbe of osteo-myelitis.

At the evening session, held under the presidency of M. TILANUS, M. Ollier presented a communication on

RESECTION OF THE ASTRAGALUS.

It was of prime necessity, the speaker maintained, to remove the astragalus in disease of the ankle-joint, in

order to secure a speedy cure and to prevent relapse. The result of the operation is a shortening of the member of about two centimetres, but the general configuration of the foot is not seriously altered. An early recourse to extirpation of the astragalus, and, if necessary, also *évidement* of the malleoli, would often obviate the necessity of amputation.

M. J. Boeckel read a paper on

EARLY TREPHINING IN FRACTURES OF THE CRANIUM.

The credit for the introduction of this method was due to Sedillat. The author had practised it in some ten cases and declared himself a firm believer in its utility. It was a perfectly safe operation when proper antiseptic precautions were taken, and it transformed an irregular and jagged osseous wound into a smooth one. In order to be of any avail, however, the trephine should be used as soon as possible after the injury had been received.

M. Demons presented a short communication upon the

INDICATIONS FOR LATE TREPHINING FURNISHED BY THE DOCTRINE OF CEREBRAL LOCALIZATIONS.

He believed that we had in the study of cerebral localizations a sure guide, even when every external evidence of the traumatism had been obliterated, and he did not hesitate to incise boldly, even removing the cerebral envelopes and penetrating the brain substance if no superficial lesion was discoverable at the point indicated.

M. Bouvet regarded trephining as a rational and safe procedure, and he advocated its immediate employment in fracture of the skull.

M. Nicaise read a note on the

SUTURE OF NERVES.

He thought the operation was a useful and necessary one, hastening repair, and, at the same time, free from danger with the observance of antiseptic precautions.

The day's proceedings were closed by the reading of a paper on

CATARACT OPERATION BY EXTRACTION,

by M. Panas. The paper was discussed by M. Galezowski and others.

WEDNESDAY, APRIL 8TH.—THIRD DAY.

M. Alphonse Guérin, Honorary President, in the Chair.

M. Thiriar, of Brussels, read a paper on

URINARY ANALYSES IN ABDOMINAL SURGERY.

The points of special importance were the proportion of urea prior to the operation, and that of the chlorides after. In the case of an abdominal tumor, when the daily amount of urea excreted, becoming gradually reduced, falls below twelve grains (three drachms) it may be concluded that the tumor is of a malignant nature. And, on the other hand, if the amount remains above twelve grains the tumor is probably benign. After the operation, a rapid diminution in the excretion of the chlorides and the fall of the daily amount to less than one grain would indicate imminent suppuration, while a total suppression of the chlorides is a warning of the immediate approach of septicæmia.

M. Verchère followed with a communication entitled

POLYURIA AND PHOSPHATURIA IN DISEASES OF THE BONES.

The polyuria sometimes accompanying osteomyelitis, might be due, the speaker thought, to an infectious nephritis rather than to the osseous lesion.

M. Kirmisson had studied the question of the dosage of urea as bearing upon the diagnosis of abdominal tumors, and believed that its value in this respect was over-estimated. He had operated with success on patients in whom the daily amount of urea excreted was less than four grains, and, on the other hand, had seen patients excreting sixteen to eighteen grains of urea in the twenty-four hours, who were, nevertheless, sufferers from tumors, the malignancy of which was beyond all question.

At the evening session, held under the presidency of M. Trelat, the first paper was upon

THE BEST TREATMENT OF FRACTURE OF THE PATELLA.

by M. Trelanus, of Amsterdam.

His method of treatment was by compression, massage, and passive movements, and was asserted by the author to have been followed by excellent results. The average length of treatment was forty days.

M. Richelot followed with a note on

THE FUNCTIONAL CONDITION OF THE LOWER EXTREMITY AFTER TRANSVERSE FRACTURE OF THE PATELLA.

He considered absence of bony union and separation of the fragments as of minor importance. The true cause of functional impairment after fracture of this bone was muscular atrophy. Hence the vast amount of ingenuity employed in the construction of apparatus to secure bony union was useless, and treatment should be directed to a maintenance of the muscular integrity.

M. Larger agreed in the main with M. Richelot, but thought that inflammation of the joint was also, in many instances, a potent factor.

M. Lucas-Championnière was a firm believer in the value of massage, but he thought that suture of the patella was also necessary.

M. Trélat read a paper on

OSTEOMYELITIS.

He referred especially to an insidious form of the disease, the gravity of which was very liable to be underestimated by reason of the apparently trivial nature of the symptoms. The main points in the diagnosis were rapid muscular atrophy, swelling of the bone, and a localized point of tenderness.

THURSDAY, APRIL 9TH—FOURTH DAY.

M. Rochard, Honorary President, in the Chair.

M. A. Guérin read a note on

THE BEST FORM OF DRESSING IN FIELD SURGERY.

The author contended that his method was the best, since it provided immobilization and shut off all access of microbes to the wound. His theory was that, if the atmospheric microbes entered by the veins, pyæmia resulted; if by the lymphatics, erysipelas.

M. Bousquet admitted that M. Guérin's dressing was the safest and most easily applied, but its bulk rendered it impracticable when it was necessary to transport the wounded any distance. He thought that for field surgery the best dressings were those which had for a basis carbolic acid, sublimate, or chloride of zinc.

M. Arragon favored the employment of

VALERIAN DRESSINGS IN MILITARY SURGERY.

M. Audet reviewed briefly the various dressings employed, and spoke favorably of M. Guérin's method of filtration of the air through cotton.

M. Bédoin recommended

DRESSINGS OF FILTER-PAPER,

prepared with sublimate, carbolic acid, or boric acid. A package of this filter-paper could easily be carried by every soldier.

M. Délorme opposed the introduction of individual antiseptic packets as being useless. The wounded must be attended to in the ambulances. He preferred iodoform as a dressing for most wounds of the soft parts.

M. Chauvel did not regard fresh antiseptic dressings

as practicable on the battle-field, but he thought each soldier should be provided with a dry antiseptic dressing for immediate application.

At the evening session, Baron Larrey, Honorary President, was in the chair.

M. Reclus read a paper entitled

THE COMPARATIVE VALUE OF LUMBAR AND ILIAC OPERATIONS FOR ARTIFICIAL ANUS,

in which he expressed a preference for the iliac operation as one of less gravity and of greater ease of performance.

M. Polloson related a case of rectal cancer in which he performed the iliac operation for

ARTIFICIAL ANUS WITH OBLITERATION OF THE LOWER END OF THE GUT.

M. Verneuil was opposed to this method of treatment, as he thought the prognosis might be rendered more grave by the presence of fecal matters in the occluded lower portion of the intestine.

M. Trélat was not in favor of abandoning entirely the lumbar operation.

M. Kirmisson said that closure of the iliac anus was often caused by the aponeurosis of the obliquus externus, and he proposed division of this aponeurosis by a T-shaped incision.

M. Boeckel then read a paper on

RESECTION OF THE HIP IN COXITIS, ITS INDICATIONS AND ITS ULTIMATE RESULTS.

The following were the conclusions of the author: 1. Suppurative coxitis in a young subject cannot be cured until the head of the femur is luxated or destroyed. 2. Resection is not in itself a dangerous operation, but only by reason of the general condition; the greater number of deaths, with or without resection, are due to pulmonary or meningeal tuberculosis. 3. The earlier a resection is performed and the less extensive is the operation, the more certain and speedy is the cure. 4. The arrest of development is slight after early resection, but is more considerable if the operation has been long deferred. 5. Tuberculosis of any of the internal organs is a contra-indication to resection of the hip, but albuminuria is not, as it is susceptible of cure after removal of the diseased bone.

M. Ollier was long opposed to resection, but he now favored the operation in certain cases. He distinguished between true and false articular tuberculosis, the diagnosis in any given case being only possible by the test of inoculation. He distinguished also between acetabular and femoral coxitis, the former being the more grave. In suppurative coxitis he did not resort to immediate resection, but tried first the effects of drainage.

M. Leriche spoke favorably of

ASPIRATION IN SUPPURATIVE HIP DISEASE.

M. Trélat said that it was necessary to bear in mind the fact that there were certain cases of pseudo-coxalgia, presenting symptoms of hip disease with the formation of abscess. It was not always possible to decide in the first instance whether the joint was involved or not, and therefore resection should not be undertaken rashly.

M. Verneuil was not an opponent of resection, as he had performed the operation himself in certain cases, but he thought it should be reserved for cases rebellious to other methods of treatment.

Friday, April 10th—Fifth Day.

M. Koeberlé, Honorary President in the Chair.

M. Cozin read a paper on

TREATMENT OF COLD ABSCESSES BY ABLATION AFTER SOLIDIFICATION.

It was necessary, the author said, to remove the wall of a cold abscess in order to prevent a return and an extension of the disease to the neighboring parts. To facilitate this removal, he employed injections of melted paraffine after evacuation of the pus, and to hasten consolidation used the ether spray. The abscess was thus converted into a solid tumor, and could be dissected out with comparative ease.

M. Bouilly then read a paper on the

IMMEDIATE AND REMOTE RESULTS OF THE TREATMENT OF COLD ABSCESS.

The author maintained that the entire destruction of an external tuberculous centre may, under favorable circumstances, result in a definite cure. It may avert a fatal issue by destroying the foci of septicæmia and the breeding-places of tubercular germs. Operation is contra-indicated in tuberculosis of the lungs or fatty degeneration of the larger organs.

M. Houzel described

A NEW METHOD OF DRAINAGE IN COLD ABSCESS.

He employed a double siphon, introduced into the abscess and into a vessel containing carbolic acid or chloride of zinc, surrounded with iodoform and covered with a dressing of carbolized gauze. These two cavities, that of the abscess and that of the vessel containing the antiseptic, were thus drained the one into the other.

M. Trélat regarded the method of M. Houzel as of undoubted value, but said that there were numerous cases in which it could not be employed.

M. Pozzi related two cases of

MULTIPLE COLD ABSCESS,

treated by scraping, cauterization, and iodoform.

M. J. Boeckel read a paper on the

TREATMENT OF ABSCESSES CONNECTED WITH POTT'S DISEASE.

He favored the opening of these abscesses by large incisions, with counter openings and thorough drainage. He had had very gratifying success with this mode of treatment.

M. Verneuil formerly extirpated cold abscesses, but now preferred to treat them by the injection of an ethereal solution of iodoform He had lately treated in this way, with success, an abscess extending from the diaphragm to the knee, and containing over six pints of pus.

At the evening session the chair was occupied by M. Gross.

M. Koeberlé read a paper entitled

TREATMENT OF THE PEDICLE IN OVARIOTOMY AND HYSTEROTOMY.

The author favored ligature of the pedicle and its reduction into the abdominal cavity, and said that this method reduced greatly the risks of the operation. He preferred ligature to the use of the thermo-cautery. When suppuration occurred it was because the ligature was not perfectly aseptic.

M. Pozzi preferred extra-abdominal treatment of the pedicle when it was very vascular and long. When, however, it was, though vascular, too short to be treated in this way he employed an elastic ligature, abandoning it within the abdominal cavity. The peritoneum was very tolerant of the elastic tube.

M. Terrillon had performed thirty-six operations reducing the ligatured pedicle, and had had four fatal results, but in none of these did the ligature cause any irritation.

M. P. Segond related a case of dysphagia from stricture of the œsophagus relieved by

GASTROTOMY.

The best landmark for the stomach in this operation was, the author said, the inferior border of the liver. If the organ do not present at this point, the left index-finger is passed along the inferior border of the left lobe of the liver until it strikes the vertebral column; then

moving it a little to the left, and keeping well up against the diaphragm, the lesser curvature will be felt. This is Farabœuf's method. He preferred the simultaneous performance of fixation and opening, contrary to the usage of some surgeons in other countries, notably in England.

M. J. Boeckel related three cases of

CHOLECYSTOTOMY.

If there is a fistula and calculi are present, this operation, the author maintained, is necessary, for it hastens the cure and is remarkably free from danger. When, however, there is no fistula, the operation is more grave.

M. Thiriar had removed the gall-bladder on two occasions, and considered this operation far superior to cholocystotomy, which was only palliative, and did not remove the cause of the evil.

SATURDAY, APRIL 11TH—SIXTH DAY.

M. Tilanus, Honorary President in the Chair.

M. Chavasse presented a communication upon

INJURIES OF THE INTESTINES OCCURRING WITHOUT WOUND OF THE ABDOMINAL WALL.

He advocated laparotomy in every case. If the rupture in the gut is small it may be closed by suture, but if the intestine is torn completely across it will be necessary to make an artificial anus. The contra-indications to laparotomy are collapse, with a temperature of 95° F. or less, or lesions of the solid organs of the abdomen.

M. Maunoury related a case of

TRAUMATIC LESION OF THE KIDNEY,

with destruction of the organ and the formation of a large abscess, cured by operation. And he proceeded to discuss at length the indications for operation in injuries of this organ.

M. Pozzi argued in the main with M. Chavasse regarding the treatment of intestinal lesions, but thought that, if the laceration was considerable, it would be preferable to operate at once for artificial anus, rather than to trust to sutures. It was better also in lacerations of the stomach or bladder to establish a fistula, at least temporarily, rather than to resort to immediate suture.

M. Bouilly insisted especially on the

OPERATIVE INDICATIONS IN INTESTINAL INJURIES,

without perforation of the abdominal wall. It would, of course, be desirable to operate before the onset of peritonitis, but that is impossible, since it is the inflammation that indicates rupture of the intestine. But the character of the onset may furnish a valuable indication as to the viscus injured, since each of the secretions of the various abdominal organs reacted upon the peritoneum in a peculiar manner.

M. Demons favored free incisions in laparatomy, so that the operator might have a clear view of the injured parts. The intestinal lesions are often multiple, and some might escape recognition if the abdominal incision were too short.

M. Verneuil agreed with M. Pozzi that it was better to perform the operation at two stages; it was perhaps less brilliant, but it was safer.

M. Socin did not favor suture of the bladder. He thought, however, that surgeons were too timid in operating in vesical injuries, and he advocated an exploratory incision whenever there was a reasonable certainty of injury to that organ.

M. Monod read a paper on the

PATHOGENESIS OF SMALL CYSTS OF THE EPIDIDYMUS.

He did not believe that these were the remains of the Wolffian bodies, but that they bore a relation to sclerosis of the testicle. This sclerosis, which is chiefly pericanalicular, obliterates the tubes and causes a varicose dilatation of the portion behind the obstruction.

At the evening session the chair was occupied by M. Trélat.

At this session was held the

ELECTION OF OFFICERS FOR 1886.

The following were chosen: President, M. Ollier; Vice-President, M. Verneuil; Secretary-General, M. S. Pozzi; Secretaries, MM. Coudray, Petit, Picqué, and Prengrueber.

M. Humbert then read a paper on

THE VIRULENCE OF BUBOES CONSECUTIVE TO SOFT CHANCRES.

M. Delorme followed with a communication on

FRACTURES IN MILITARY PRACTICE.

M. Pozzi read a paper on

OSTEITIS DEFORMANS,

in which he expressed views similar to those enunciated by Paget in 1876.

M. Duret related a case of

IMPERFORATE ANUS,

the rectum communicating with the urethra. The child was operated upon by Amussat's method with an excellent result.

M. Loewenberg completed the scientific labors of the Congress with a paper on the

TREATMENT OF SUPPURATION OF THE MASTOID.

He did not favor trephining of the mastoid process, except in cases of absolute necessity.

After a brief

VALEDICTORY ADDRESS

by the President, the Congress of 1885 was declared adjourned.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 3, 1885, to May 9, 1885.

Bill, Joseph H., Major and Surgeon. Ordered for duty as member of Army Medical Examining Board, New York City, N. Y.

Spencer, William G., Captain and Assistant Surgeon. From Department of the East to Department of Dakota. S. O. 100, A. G. O., May 2, 1885.

Brechemin, Louis, Captain and Assistant Surgeon. From Department of the East to Department of the Platte. S. O. 100, A. G. O., May 2, 1885.

Davis, William B., Captain and Assistant Surgeon. From Department of Dakota to Department of the East. S. O. 100, A. G. O., May 2, 1885.

Sternberg, George M., Major and Surgeon. Detailed to attend, as a delegate on the part of the Government of the United States, the Sanitary Conference to be held at Rome, Italy, on May 15, 1885. S. O. 103, A. G. O., May 6, 1885.

Cowdrey, Stevens G., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Bliss, Tex. S. O. 65, Department of Missouri, May 2, 1885.

Wyeth, M. C., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Wadsworth, N. Y. H. S. O. 95, Department of the East, May 6, 1885.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 9, 1885 :

Dr. Hinde's Paper.—Dr. Hinde, whose paper appeared in The Record of April 25th, asks us to make the following corrections: "Case I., p. 455, instead of age *fifty-four* read *thirty-four*. The bearing of the age of the patient on the normal near-point of distinct vision and on the range of accommodation renders this correction all important. The patient's youth, however, would not permit of his service in the Indian mutiny proper, and on further questioning I have reason to doubt this part of the history. The word *pupilla* occurring several times on p. 456 should read *papilla*; p. 457, line 21 from the top, *which* should be omitted; same page, line 29, instead of *construction* read *contractions*; p. 458, line 37 from top, *notice* should read *notes*; same page, line 8 from bottom, *and* should be omitted."

Foudroyant Cholera.—Dr. James Christie, of Zanzibar, has given the most graphic account of this in his admirable book on the "Cholera Epidemics of East Africa," page 377. He says: "A near neighbor of mine sent for me about midnight to see a remarkably handsome Galla woman about twenty years of age. There had been several cases of severe cholera in the house, and I was sent for at once, and saw her within a quarter of an hour after she first felt any symptom of illness. She seemed in perfect health, except that she had been suddenly seized with vertigo and a sensation so peculiar that she was certain that she was going to die. There had been no nausea, vomiting, diarrhœa, or cramps. I examined her most carefully; there was no pain or tenderness, no coldness, nor any depression of temperature. There was only a certain wildness of the eyes, a restlessness of manner, and an anxious expression. There was no failure of strength; she could walk as well as ever, but she was pulseless at the wrists, although I imagined I detected a thread-like quivering of the radial artery now and then. The heart's action seemed unusually strong and rapid, as if the greatest cardiac power was exerted to propel the blood to the remote capillaries; but in less than a quarter of an hour she was absolutely pulseless at both wrists. I imagined the case was not hopeless, and tried to reassure and comfort her; but turning to her master, she said, 'Oh, my master!' and threw herself upon some cushions on the floor. It was most evident that hers was no fancied case of illness; no effect of a morbid imagination; no effect of fear, for there was no evidence of fear of death. It was far more like the full consciousness that the fountains of life were being sapped. In a very short time a peculiar coldness, the cold clamminess of death, set in; but coincident therewith, the most remarkable symptom of all, viz., a sensation of burning heat, not so much internally, at first, as of the surface of the body; a sensation so intense that nothing would alleviate it but the external application of cold water. Yet the body was very cold to the touch, and next the nose, lips, and tongue became cold, followed by intense thirst, which nothing but cold water could assuage. The pulsation of the temporal arteries ceased, while the carotids throbbed laboriously and spasmodically. The plump, rounded form of the body began to be effaced; the skin of the fingers, toes, hands, and feet became shrivelled, the features pinched, the eyes sunken and glaring, the voice hollow and sepulchral. Then the pulsation of the carotids ceased, the breathing became laborious, the breath was cold, the heart's action began to fail rapidly. The nervous system seemed intact; the intellectual faculties were clear, and motion and sensation were but slightly impaired. She was dead in four hours from the accession of the first symptom. There was no purgation." He noticed the same kind of attacks among children, who invariably cried without being able to explain what was the matter with them. They seemed instinctively to know the deadly nature of the seizure. He saw a man who felt himself taken ill, who at once went to his house, wrote out directions about his property and the liberation of his slaves, and was dead in four hours. He was perfectly calm and collected; had not the least fear, but knew he was going to die. Some negroes were attacked while going along the streets. While engaged in burying the dead, it was no unusual thing for them to be supported back to their huts, there to die, be rolled up in a mat, and carried back to the graves in less than six hours. The well-water in Zanzibar was horrible, and all these severe attacks could be traced to drinking freely of it while the stomach was empty.

Gone to America!—Under this caption the *Allgem. Wiener med. Wochenschrift* bewails the loss of the original drawings for Jaeger's "Atlas of Diseases of the Fundus of the Eye," which it says were recently purchased for Professor Norris, of Philadelphia, for 4,500 florins ($2,250). There are in all about one hundred sheets, each one drawn by Jaeger himself; and to give an idea of the amount of labor which they represent, it is stated that the author spent sometimes two hundred hours in drawing and coloring a single page.

Punished for Neglecting Antiseptic Precautions.—A midwife was recently arraigned in Breslau for causing the death of a woman whom she had attended in confinement. The patient died of septicæmia, due, it was complained, to the neglect of the accused to wash her hands in a carbolic solution prior to commencing her attendance. The midwife said she had washed her hands in carbolized water before leaving her home, but this was declared insufficient and she was condemned to six weeks' imprisonment.

Students at the University of Naples.—The number of students entered at the University of Naples for the current scholastic year reaches the very respectable figure of 3,627. Of these, 1,472 are law students, and 1,383 students of medicine, the remainder being distributed through the scientific and classical schools.

Death of Professor Tanturri.—Dr. Vincenzo Tanturri, Professor of Dermatology and Syphilography at the University of Naples, died on January 31st of the present year. Professor Tanturri, in connection with Dr. Cavallo, founded the journal *Il Morgagni*. He was in his forty-ninth year at the time of his death.

Change of Name.—The Parisians are apparently so fond of change that they cannot even pass by the hospitals. The Hôpital des Tournelles is now to be known as the Hôpital Andral, and the Hôpital des Mariniers as the Hôpital Broussais.

An Electric Lamp for Microscopical Illumination has been devised by Mr. L. Nyrop, an instrument-maker of Copenhagen. It is so constructed as to be applicable to any microscopical stand and can be used for either reflected or transmitted illumination.

Original Articles.

NON-DEFORMING CLUB FOOT.

WITH REMARKS ON ITS PATHOLOGY.[1]

BY NEWTON M. SHAFFER, M.D.,

CLINICAL PROFESSOR OF ORTHOPÆDIC SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; ATTENDING SURGEON IN CHARGE OF THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL; ORTHOPÆDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

THE disabling conditions which are entailed by club-foot are too well known to warrant any extended description. It is not my object on this occasion to dwell upon this point, but to call attention to a condition which, though less conspicuous than true club-foot, is accompanied by many of its annoyances, and in some cases even by its disability; and which I think has not been described or noticed by writers upon either general or orthopædic surgery. At least, I have been unable, after an extended search, to find any such record; and I have also asked those most likely to have information upon the subject, and the result has been entirely negative. It may be well also to say a word in explanation of the name I have given this condition—non-deforming club-foot.[2] It is an apparent solecism, but I think it best expresses my meaning, and certainly it is no worse than "angular curvature," of which we often hear.

In non-deforming club foot all the conditions found in certain forms of talipes exist, with the exception of the exaggerated deformity. That is, there is a loss of normal relation between the articulation at the ankle and the muscles which act upon it, involving also in many instances the tarsus, producing a condition which prevents normal flexion at the ankle-joint, and modified mobility, with slight deformity at the tarsal, metatarsal, and phalangeal articulations.

With this state of affairs, we find as a result, varying with the conditions present, actual disability, pain, sometimes very severe, in various parts of the foot, ankle, leg, and even reflected to the lumbar region, and tender and inflamed articular surfaces, especially at the junction of the first metatarsal bone with its phalanx.

If these effects be wanting, we may have only an awkward or peculiar gait associated with painful callosities and corns at various points upon the foot.

The integrity of locomotion depends to a great extent upon a proper degree of flexion and extension at the ankle-joint, and upon a normal condition of the plantar arch and plantar tissues. As, however, the conditions which will be considered on this occasion depend upon a modified flexion at the ankle-joint, and a contracted state of the plantar tissues with their sequelæ, we will omit a discussion of other conditions except as they may throw light upon the subject. Nor is it intended to discuss at length the mechanism of the ankle and the various bones of the foot. We have certain and easily demonstrated clinical conditions to account for, and an extensive dissertation upon mechanics is not necessary.

[1] Read before the New York Orthopædic Society, February 26, 1885.

[2] During the discussion of this paper the title I have chosen to designate the condition described met with criticism. No one, however, suggested a better name, unless that used by Dr. Berg is such. In his remarks he referred to "incomplete club-foot." But "incomplete club-foot" does not express my meaning. The club-foot is complete in all its essential particulars. The deformity is so slight, however, that it has heretofore escaped the observation of surgeons and writers on deformity. Hence it is that I retain the title notwithstanding the friendly criticism of my colleagues.

But there are a few points which may help us, and I will briefly allude to them.

First, as to the ankle. Its function, except in extreme extension, is that of a plain hinge-joint. In the conditions we have to deal with, flexion and extension are the only movements to be considered. Extension of the foot, in the adult, is limited at about 135°, or 45° more than a right angle, using the long axis of the tibia as the plane of measurement. Flexion stops at about 70°, or 20° less than a right angle (see Fig. 1). The

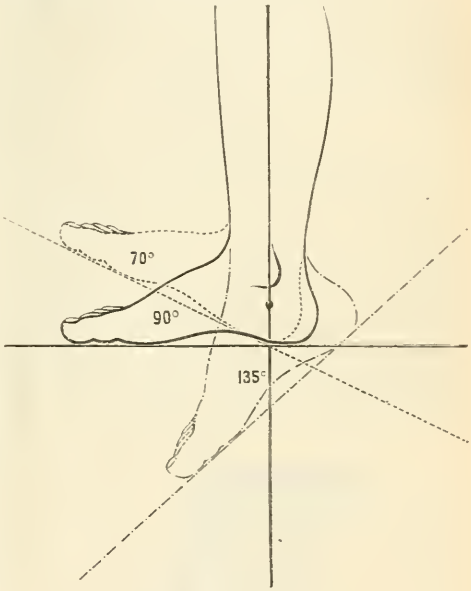

FIG. 1.—Modified from Noble Smith.

position of the foot in standing upon an even surface, with the knee in full extension, is about 90°. The amount of flexion and extension varies in different individuals, but these figures, based upon actual experiment and measurement, represent, I think, the average of normal movement in the living adult subject.

We should remember the general structure and function of the tarsus and metatarsus in sustaining the weight of the body, and especially the relation of the plantar tissues to the arch formed by these bones, and the articulations between them. Grossly speaking, the plantar tissues represent the bow-string of a bow, and they, with the articulations in the arch above, furnish the basis upon which elasticity is furnished to the arch. With each step the arch is "sprung" slightly in normal locomotion; but if we have a contraction of the plantar tissues, this elasticity is destroyed or interfered with, and the "ball of the foot" is drawn toward the heel to a greater or less extent. The os calcis does not move forward toward the "ball of the foot," especially if the gastrocnemius muscle is shortened. In calcaneus, where the gastrocnemius muscle is paralyzed, the plantar tissues contract and draw the heel toward the metatarsus and phalanges. In each

case the least resisting part is drawn toward the more fixed part, and modifications of the tarsal arch of different characters are seen. In each case also the tarsal arch is exaggerated; and, while we can have a calcaneo-valgus with a contracted or shortened plantar fascia, it is only, in my experience, when the gastrocnemius muscle is paralyzed or weakened. The *inner* part of the foot is, so to speak, the *varus part*, and, with the exception above noted, a contraction of the plantar tissues results in a varus with an adduction of the tarsus and metatarsus.

The outer part of the foot is not so likely to be shortened antero-posteriorly as is the inner part. The outer part of the foot in normal locomotion touches the floor at each step, and is deprived of elasticity in the same sense as the plantar arch. It is intended for direct contact, and affords an unyielding support. It becomes affected secondarily in club-foot, when pes cavus results.

Practically speaking, with the exception noted, we can divide the foot longitudinally, as applied to the deformities of club-foot, at the mid-tarsal and mid-metatarsal region, just as we can divide the foot transversely at the medio-tarsal joint. As before stated, we do not expect to find a shortened plantar fascia in valgus, nor do we look for an elongated condition of the plantar tissues in varus. If the plantar arch gives way, valgus results. If the arch is exaggerated with the exception noted, we have one of two deformities. First, the antero-posterior contraction in the plantar region draws the ball of the foot nearer the heel, and brings the metatarsal bones more nearly in a line with the long axis of the tibia, producing that position so frequenlty seen as the accessory of pes equinus, with little or no varus; or, secondly, we find a true varus with the metatarsal bones thrown into an adducted position, *i.e.*, toward the mesial plane. In exaggerated cases both of these conditions may exist. In non-deforming equinus, of the type now under consideration, there is generally a slight exaggeration of the tarsal arch, with little or no adduction of the tarsus and metatarsus. The deformity at the tarsus, in short, is antero-posterior, and not lateral; and while we may have and frequently see a non-deforming club-foot presenting as a valgoid state, it is not of this condition that I wish to speak.

FIG. 2.

Depending upon the portion of the plantar tissues affected, we have as a result of the condition now under consideration a shortening of the inner half of the foot. The inner part of the foot contracts, antero-posteriorly principally, with the result of making the plantar arch noticeably hollow just posterior to the junction of the first metatarsal bone with its phalanx. (See Figs. 2 and 3.)

The two inner metatarsal bones assume a position more nearly approximating a vertical line, and the whole of the inner half of the distal part of the foot is thrown out of normal relation to the rest of the foot and the body.

The three outer metatarsal bones are not normal under these circumstances. Their relations to the other parts of the foot are, however, considerably less disturbed than are the two inner ones.

And now, what happens as to the muscular relations? The flexors of the ankle-joint proper are unable perform the act of flexion. Owing to the plantar resistance or the gastrocnemius resistance, or both, and the altered relation of the metatarsal bones and the tarsus to the

FIG. 3.

ankle-joint, the distal part of the foot passes beyond the complete control of the ankle flexors. A peculiar feature of non-deforming club-foot now presents. The extensors of the toes act as assistant flexors of the ankle, and in doing this it is necessary that the extensors should complete their function as such before they can aid the crippled ankle-joint flexors. Hence, all those who have non-deforming club-foot with plantar or gastrocnemius contractions, when asked to flex the ankle, put the toes in extreme extension in the effort to accomplish ankle-joint flexion.[1]

Not only, then, are the inconveniences and disabilities of non-deforming club-foot due to contractions of the muscular tissue and fasciæ, with subsequent changes in ligaments and bone—thus putting the complicated foot- and ankle-mechanism at a disadvantage—but also to a very important loss of elasticity at the tarsus. When this elasticity is lost completely in simple flat foot, the gait and the disability are easily recognized. When the elasticity is modified by a shortened state of the plantar tissues and the arch is exaggerated, a different disability is present, the principal features of which I shall soon point out.

It is unusual to find a gastrocnemius shortening without some changes in the plantar tissues also. When, however, as sometimes happens, the gastrocnemius shortening is the principal factor in non-deforming club-foot, flexion may be arrested at any point about the right-angled position. Most frequently the foot stops at 90°, or a little more or less. An awkward gait is apt to oc-

[1] (See again Figs. 2 and 3.) The toes are thrown into extreme extension, and the tibialis anticus stands out prominently, as seen in Fig. 3, and yet the patient could not flex the ankle sufficiently to raise the "ball of the foot" to the 90° line. So also in Fig. 2, the plantar depression and the prominent and calloused "ball" is very evident. The patient from whom these engravings were made, came to the Orthopædic Dispensary suffering from severe pain in the thigh, and was limping badly. Only one limb was affected. It was supposed by the physician who sent the patient to the institution that she was suffering from hip-joint disease. All her symptoms arose from the slight non-deforming club-foot, which escaped the notice of the entire assistant staff of the dispensary. The patient was exhibited at the meeting after the reading of this paper. It is this condition which constitutes true non-deforming club-foot. The patient was unaware of her condition; many physicians examined her without discovering her true trouble, and it required a close examination and tests to demonstrate the slight deformity upon which depended the pain and disability.

cur with gastrocnemius shortening and slight plantar trouble; while pain, "gouty big-toe joints," and disability are apt to occur when the plantar troubles are in excess.

If the condition which I have tried to describe exists, while the patient is aware that something is radically wrong, he does not recognize the cause. The trouble, not enough in many instances to warrant belief that a surgeon could be of service, comes on gradually, and is frequently a process of slow growth. It becomes a sort of "second nature" to the individual, and he comments on his disability or awkward and peculiar gait; he curses his gouty toe, or condemns his shoemaker, or applies iodine or cocaine to his painful ankle or tarsus.

Perhaps he takes a long course of "anti-rheumatic" or "anti-gout" remedies under the direction of intelligent and reputable physicians. He probably spends considerable money in obtaining temporary relief at the chiropodists, and looks in vain for the, as yet, undiscovered "anatomical" shoemaker. But the sought-for relief does not come.

Let us suppose that, under these circumstances, a person afflicted with non-deforming club-foot presents for examination. He removes his shoes and stockings, and presents his feet for inspection, occupying a seat upon a chair which is near that of the surgeon. Under these circumstances the foot falls at once, and naturally into a position of *pes equinus*, and all that one notices, unless his attention is especially directed to some other point, is the prominent "big-toe joint" with its swollen and tender surfaces, or the painful corns at different points. The real elements of the trouble are lost in the natural "toe drop" of the position taken by the patient. If, on the other hand, the patient is really disabled by "an exacerbation of the gouty symptoms," and is confined to his bed, again the equinus position of the foot is apt to deceive, and the attention of the surgeon is directed, not to the cause of the trouble, but to an effect. Rest and local applications, with or without constitutional remedies, are generally prescribed; and the rest produces relief. The patient goes about again after a few days, only, however, to inflict an injury upon the vulnerable tissues, and to suffer another relapse; when again the "gouty toe" receives attention.

Now let us see what a critical examination of a patient in this condition shows. After examining the foot as to sensitiveness, etc., and inspecting the inflamed big-toe joint, ask the patient to stand up. He will probably be able to stand erect with his feet upon the floor, in the "heel and toe" position; for the weight of the body acts as a flexor and the elasticity of the tarsal arch is not wholly lost. There is no apparent deformity, no great variation from the normal. The feet are, perhaps, not quite straight, but then the patient will tell you that it has always been so; as if this made it right. He can walk across the floor without apparent trouble. Ask him now to stand squarely against the wall, with the knees in full extension; ask him to throw the weight of the body upon one limb, while he attempts to flex the opposite ankle-joint. He will be surprised to find that he has little or no flexion. It is then that the toe extensors come into bold relief as aids to ankle-joint flexion. Test both ankles in this way. Perhaps both will show modified flexion; more generally only one will be affected to a marked degree; the other being slightly crippled only. In some cases a marked plantar resistance, accompanied only by a slight gastrocnemius contraction, permits tolerably good ankle flexion, but not enough to raise the "ball of the foot" far from the floor. Still better, put the patient in the recumbent position, and ask him to flex the ankle with the knee straight. He cannot bring the "ball of the foot" into the normal plane of the heel, the former dropping from one-fourth to three-fourths of an inch below the latter. The resistance cannot be overcome by voluntary muscular effort, though the patient concentrate all his energies in this direction. Again the toe extensors come prominently into play, and, in some cases, the phalanges assume a position nearly at right angles with the long axis of the first metatarsal bone. In this position try manual pressure. You find that the tissues, both plantar and post-tibial, form a resistance which you cannot overcome. You only render the resisting tissues more tense by your efforts. You cannot do more if you give an anæsthetic. The conditions found are those of true club-foot; the contraction and malposition are permanent. The sequelæ are there, and the condition is one that, in many instances, demands treatment.

Non-deforming club-foot may exist, and does frequently exist, without the attending evils mentioned in the foregoing remarks. I have tried in this sketch to outline a typical case, accompanied by more than simple inconvenience. There are a large number of cases, in young and growing girls especially, where inability to flex the ankle does not produce more than a slight inconvenience, or an awkward carriage or a peculiar gait. I shall refer to these cases farther on.

It will be seen that non-deforming club-foot of the class which I shall dwell principally upon on this occasion approximates the conditions found in equinus or equino-varus. There is another condition which time does not permit me to discuss, viz., simple flat-foot, that presents a valgoid condition. But here in certain conditions there is a shortened gastrocnemius with relaxed plantar tissues and a flattened arch.

Nor can we stop to consider inflammatory flat-foot. It has certain signs and symptoms which render any remarks on differential diagnosis unnecessary, for there is no primary local inflammation in the class of cases I wish to describe.

The inflammation in true non-deforming club-foot is the effect of the altered articular relations and the long-continued and abnormal pressure. The inflammation, happily, with its attendant pain, swelling, corns, and callosities, speedily ceases when the cause is removed, and the parts are restored to an approximately normal position and relation. There is only one exception, perhaps, to this rule regarding primary inflammation, and that is in chronic sprain, when we have, in certain instances, a condition which I have ventured to name traumatic non-deforming club-foot.

Non-deforming club-foot may occur at any age. I have seen it in infancy, when doubtless its etiology is the same as that of congenital club-foot. It occurs rarely as an acquired condition in children, though often the "good result" of many surgeons after tenotomy and treatment leaves behind it a condition like that I have attempted to describe. It is seen very frequently during the period of second growth—the adolescent period—in both sexes, when, at that particular age, there are not apt to be many important sequelæ. It usually does not reach its full development until adult life and full growth is attained.

It occurs more frequently in the female sex, and *when looked for*, is found sometimes in rapidly growing girls, and especially in those whose growth has been apparently arrested before the average height is reached. And what is very important, and to a certain extent remarkable is this: *it is found very often associated with true rotatory lateral curvature of the spine.*

The discovery of the co-existence of non-deforming club-foot with true lateral curvature was the result of what proved to be a logical conclusion from the study of certain muscular conditions seen in the true club-foot of children affected with unilateral arrest of development from the, as yet, obscure lesion which occurs in the motor tract of the brain. I have seen many cases of this character, and, after examining a case of this kind with Dr. Berg, the electro-therapeutist of the Orthopædic Dispensary and Hospital, in 1881, I remarked to both Dr. Ketch and Dr. Berg, "The muscular conditions found in this boy's foot remind me of the muscular conditions found in true lateral curvature;" and I further said that I would examine my cases of lateral curvature more care-

fully and find out the muscular conditions at the ankle-joint. Soon after this I was called to see a patient with true lateral curvature and marked rotation in the mid-dorsal region, Miss C. S——, eighteen years of age, who had been placed under my care by Dr. T. G. Thomas. After inspecting the curves and modifying the apparatus, I asked permission to examine the ankles. The patient had on either side a typical non-deforming club-foot. The gastrocnemii were short, the plantar tissues were contracted, the prominent toes were there, callosities were present; indeed, all the signs and all the conditions that go to make up a true case of non-deforming club-foot were found. The peculiar gait and "rheumatic pains" of the patient were accounted for, and the slight "ankle weakness" which existed in this young lady was explained. Since that time I have examined many cases of true scoliosis, and while some of them escape, there is in a large number a modified ankle-joint flexion due to muscular changes and muscular contracture. And I have examined, as opportunity presented, young girls especially, who have other troubles than scoliosis. It sometimes happens that in a case where there is no apparent cause, the non-deforming club-foot exists, though the percentage is very small as compared with the scoliotic subjects. It does not follow, therefore, that all scoliotic girls should necessarily have ankle-joint complications, but fully, or over one-half of my cases present non-deforming club-foot as a condition that accompanies true scoliosis. A portion of my notes on this subject have been mislaid, and I cannot, I am sorry to say, give accurate figures. One thing, however, may be regarded as certain; and that is, that to the mammary atrophy, the shortened leg, and the other trophic signs of true lateral curvature may be added the non-deforming club-foot, which is more frequently present, I think, than either the unilateral shortening or the mammary atrophy.

This, to say the least, coincidence is somewhat remarkable, and may yet throw some light upon the etiology of true scoliosis by directing our attention toward the central nervous system in our efforts to find the ultimate cause of this, as yet, obscure condition.

The conditions found in non-deforming club-foot of the type especially that accompanies the lateral curvature are certainly suggestive. There is no paralysis, the electrical reactions of the muscles are normal and sensation is unimpaired. There are, however, sometimes marked unilateral differences, especially at the upper and lower extremities, both as to length and circumference. There seems to be, in many cases, a unilateral difference of growth. Even if one leg is shorter than the other, muscular power, with the tests I have applied, seems to be normal. So far as the ankle and the non-deforming club-foot are concerned, it is found that as soon as the mechanical relations are restored the patient is able to perform all the movements normally. The reflexes are apt, especially the patellar tendon reflex, to be exaggerated, though in some instances this is not so. Again, it frequently happens that the non-deforming club-foot is not present in the shorter limb, but in the longer one, as if the bone had, so to speak, outgrown the muscles (see remarks under Class 4). There is no evidence of motor-spinal complications (eliminating, of course, the cases referred to under Class 1). It seems to me that some cause, congenital or acquired, has produced, in some cases, a unilateral, in others a bilateral misdirection of growth rather than a typical arrest of development, which, in some instances, shows itself at the neck (true torticollis); at the spine (true scoliosis); or, at the feet (non-deforming club-foot). In non-deforming club-foot the changes are not always apparent in early life. Like true torticollis, and, as I believe, like true scoliosis, the changes are not apparent till growth develops them. But as growth occurs, and especially as the second or adolescent period of growth appears, slight and often unnoticed defects come into prominence, and when full growth is attained, as in the conditions found in non-deforming club-foot, they become more apparent, and they are frequently disabling. In torticollis these changes are apparent in early life; in scoliosis they are noticed most frequently in adolescence; in non-deforming club-foot they are often entirely unnoticed in childhood, become apparent at puberty, and are burdensome later in life. If we accept the lessons taught us by neurology we must look, not to a peripheral lesion for our cause, nor to habit, nor to the spinal cord, but to the, as yet, little, pathologically speaking, understood motor tract of the brain for the primary lesion which causes the slowly progressive changes in the muscles, and, secondarily, in the bones, joints, and fibrous tissues.

Aside from the reasons and inferences given here, I have other grounds for my belief, as expressed above, and the best way to express them is to classify the subject as far as is possible from a pathological standpoint.

We may have a condition of non-deforming club-foot from five different causes: 1, Non-deforming club-foot seen after polio-myelitis anterior; 2, non-deforming club-foot which follows simple and uncomplicated malposition, habit, etc.; 3, non-deforming club-foot produced by traumatism, sprains, etc.; 4, non-deforming club-foot found after the infectious diseases of childhood, especially diphtheria and scarlet fever; 5, the non-deforming club-foot due, as I believe, to some remote trophic disturbance, and seen quite frequently co-existing with true lateral curvature.

As briefly and as concisely as possible I will refer to these different conditions:

1. Non-deforming club-foot seen after polio-myelitis anterior. As long ago as 1865, I noticed quite frequently that when both lower extremities had been paralyzed and one had apparently entirely recovered; or in some cases, where the history pointed to only a unilateral paralysis, as a sequel of polio-myelitis anterior, that at the ankle joint and at the tarsus of the so-called "well foot," certain abnormalities would appear. In other words, and as a matter of illustration, a certain amount of varus or equino-varus would be present. Since that time I have seen many instances of this kind, and I have frequently been consulted by my patients, in this condition, for advice regarding the "well foot." Indeed, I have come to consider it almost exceptional, after an analysis of many cases, to find a foot free from contraction, and perfectly normal after recovery from polio-myelitis in childhood and affecting one or both lower extremities. As a rule, however, the inconvenience produced by the non-deforming club-foot, under these circumstances, is so slight compared with the great disability of the affected side or limb that little or no notice is taken of it either by the patient or surgeon. But the conditions found at the ankle and tarsus of the limb which apparently has recovered have often been sufficient to produce just the troubles I have pointed out; and as before remarked, I have benefited several patients greatly by treating the apparently slight contractions found at the tarsus and calf. In many cases the amount of non-deforming club-foot, under these circumstances would be considered a great annoyance and burden if the disabled limb were a normal one in all respects.

Under these circumstance we have a well-recognized pathological condition to account for our non-deforming club-foot. The acute inflammation in the anterior horns of the spinal cord is the cause of this condition, and the imperfect recovery leaves, primarily, a slightly disturbed muscular, and, secondarily, osseous and ligamentous changes which make a complete picture of non-deforming club-foot. In some of these cases I have found deficient power in the tibialis anticus muscle, but not generally. In the majority of cases, there is no real loss of power that can be defined or measured with the faradic current, and unlike the non-deforming club-foot that I have attempted to describe in the foregoing pages, it frequently appears in childhood as soon, indeed, in some cases, as the more marked deformity and atrophy at the more extensively disabled limb. It, like the trophic non-

deforming club-foot of Class 5, becomes more annoying in adult life unless it receives early attention; and I make it my rule now to treat these contractures, however slight, in children or in even older persons.

I was inclined at first to attribute what I have since called for want of a better name, the trophic non-deforming club-foot to a slight and unobserved attack of polio-myelitis, occurring early and remaining undiscovered until adult life brought the defect to the notice of the victim. And I am not certain that, in some cases, this is not true. But the absence of early symptoms, the frequent limitation of the trouble to the tarsal tissues principally, the normal reaction of the muscles, the presence of an exaggerated tendon reflex at the knee, and the absence of specific atrophy, or rather the presence, in many cases, of large, well-formed, and strong limbs, seems to exclude polio-myelitis from the larger group of cases, nor can I find in any of my cases any history of an illness like that which marks polio-myelitis. There is in none of my cases any history which leads me to think of the spinal cord; on the contrary, the clinical picture points to another motor tract, viz., that of the brain.

Where a marked equinus or equino-varus ensues after polio-myelitis, and frequently after years of treatment, the best result often obtained leaves an ankle-joint that cannot be flexed to a right angle. Of course voluntary power over the flexors is gone, and the patient in attempting to walk, cannot bring the heel squarely upon the floor. This very seriously interferes with locomotion, especially if the quadriceps extensor muscle is impaired by the central lesion. We have here another form of club-foot which needs attention, and which can be greatly relieved without tenotomy. Indeed, I have been very greatly surprised in several cases to find considerable muscular power developed by overcoming the contractions without tenotomy, giving the patient the opportunity of flexing the ankle while standing upright, using the weight of the body as a mechanical aid to its production.

2. Non-deforming club-foot produced by malposition, habit, etc. It will be noticed frequently that patients who have been for a long time in the recumbent position, or who have a shortened lower extremity, present a slight amount of equinus. In these cases there is not much tarsal shortening, and in all of them the deformity is overcome generally very easily by manipulation, or what is better, use of the limb and joints. There is no organic trouble, or complicating inflammation, or polio-myelitis back of the contraction, and as the trouble is functional, restoration soon follows if the patient has full functional use of the limb. Habit, or continued malposition, is not, I am assured, the cause of true non-deforming club-foot; of that kind, for example, which is associated with the lateral curvature. We can, again, for example, have a lateral curvature due to habit, but not the true scoliosis that is accompanied by rotation. The non-deforming club-foot of habit is not the club-foot of scoliosis, where simple habit, I am sure, does not enter into the etiological factors at all.

A great deal has been said by both the medical profession and the laity regarding the subject of high-heeled shoes as a factor in the production of various ills. As regards this element, I may say at once that all the cases I have seen of non-deforming club-foot, due to obscure causes, have worn low-heeled boots, and have rarely worn tight shoes. High heels afford sometimes a temporary relief to the victims of non-deforming club-foot. But the advantage gained, as to the shortened gastrocnemius, is soon lost by crowding the tarsus and foot into a very uncomfortable and painful position, and high heels, if tried, are soon discarded. To those who have plantar contractions alone, these high heels produce, as one of my patients said to me, "perfect misery." Happily, the "anatomical" shoemakers are using low heels and broad soles. These are the shoes sought for by those who suffer from non-deforming club-foot.

So far as the habit of wearing high heels is concerned, it may be dismissed as a factor in the production of obscure cases of non-deforming club-foot that I have attempted to describe.

3. Non-deforming club-foot produced by simple traumatism, sprains, etc. I need not stop here to dwell upon the conditions found in chronic sprain. Suffice it to say that, as a result of the injury, seconded by the malposition and reinforced by adventitious inflammatory products, there results a condition of affairs which, after the acute symptoms subside, leaves the foot in a position of slight deformity. This deformity is almost always an equinus, with or without some slight lateral malposition, and, as is well known, complete disability frequently results.

Such a case presented at my office on May 24, 1882, having been referred to me by Dr. A. L. Loomis. Mr. S——, aged sixty-five, residing in Central New York, sustained a severe sprain of the right ankle in July, 1881. He was treated by the usual methods and by competent men, with a not unusual result. He came into my office on crutches, which he had been using ever since the acute symptoms had subsided, about nine months. He had suffered very much, and had tried almost everything, he said, and had now come to New York with the idea of having the foot amputated if he did not find relief.

It is needless to transcribe my notes in detail. I need only say that it was a bad case of chronic sprain. The foot was in a position of extension, with slight tarsal contraction. The patient was unable to stand upon the foot, or to bear any weight upon it; first, because the shortened post-tibial muscles and tissues prevented any motion whatever in the direction of flexion; and, secondly, because any attempt in that direction gave great pain. He was a man of great strength of character, and made every effort to flex the ankle, but without any success.

The indications seemed very plain; I knew that if I could elongate the shortened gastrocnemius and lengthen even slightly the plantar tissues, thus affording even slight ankle-joint flexion, the patient would have normal joint surfaces to use, and not the abnormally sensitive ones that were then in contact. I asked him if he would consent to an experiment that would probably hurt somewhat. I stated if he objected to the pain I might occasion, I could give him an anæsthetic, but told him if he remained under my care the experiment must be tried. He told me to do what I saw fit, and that he could bear any pain I might inflict. I put the foot in an extension shoe,[1] and applied traction to the extent of the patient's endurance. He walked alone and unaided that day. Eight applications of the extension shoe, covering as many days, relieved this man so completely that he returned home using only a cane. He soon discarded even that.

One more illustration of the benefit of the extension shoe in the traumatic non-deforming club-foot.

A young lady, Miss P——, aged nineteen, consulted me on May 2, 1884. She had sprained her ankle in getting out of a sleigh, in December of the previous year. After a prolonged treatment she was told that she was well, and that she must walk. She tried to walk and failed. Gradually she became able to walk a block, or, at most, two blocks. This slight effort occasioned pain of an excruciating character at the medio-tarsal joint. I saw her five months after the accident, and she was still unable to walk more than two blocks. Her general health was beginning to suffer and her friends were very anxious about her condition.

Upon examination of the foot, I found a shortened gastrocnemius and a contracted plantar fascia. The ankle could not be flexed beyond ninety degrees, and

[1] I have described the "extension shoe" in an article on "Traction in the Treatment of Club-foot," in the New York Medical Record for November 23, 1878. The present article will soon be followed by another, giving the author's more recent experience with its use, and with detailed instructions as to its management in both non-deforming and true club-foot.

any effort to carry it further gave rise to pain. The patient could not voluntarily flex the ankle above ninety degrees. With the other ankle flexion was normal, and there had been no trouble with the affected joint prior to the injury.

Nine applications of the extension shoe, covering two weeks, completely relieved this patient. She has had no return of the trouble since.

4. The non-deforming club-foot found after the infectious diseases of childhood, especially diphtheria and scarlet fever. Dr. A. Jacobi on a recent occasion (*vide* the New York *Medical Journal*, August 9, 1884) calls attention to a condition which may throw light upon certain cases of non-deforming club-foot. His remarks are upon "The Relation of Over-nutrition after the Acute Fevers of Childhood to Bone Disease." After mentioning the fact that children not only seemed, but really were taller, Dr. Jacobi says, "the body became taller by an elongation of the bones; the bones grew by a rapid proliferation about the cartilage."

I have seen two cases recently which seem to substantiate this statement, and which further seem to demonstrate that during this rapid growth of the bones the muscles do not keep pace with them. The result is a considerable non-deforming equinus in each case. It is several months since the acute infectious process subsided, and yet there remains a slight but easily demonstrated non-deforming club-foot, and more, I am quite sure, than that which results from simple recumbency. And I have seen several cases where scarlet fever and diphtheria left behind as their legacy a lesion producing a slight hemiplegia, and trophic disturbances resulting in a non-deforming club-foot. Indeed, it is well worth while for us to investigate the relation of these infectious diseases as etiological factors in the production of such conditions as those found in non-deforming club-foot, both in children and in adults.

It may be in place to remark here that in a large number of young girls that I have examined for lateral curvature, and in whose history an early attack of diphtheria or scarlet fever was the only important or tangible etiological factor, I have found an easily demonstrated non-deforming club-foot. If, as may be the case, the etiology of true scoliosis and the accompanying ankle-joint contraction are the same, we may find that the infectious diseases of childhood play an important rôle in their production.

5. The non-deforming club-foot due, I believe, to some remote trophic disturbance, and seen quite frequently co-existing with true lateral curvature. The first case of this kind of which I can furnish any notes was seen in consultation with Dr. M. Putnam Jacobi, on April 22, 1880. From exhaustive and complete notes furnished by Dr. Jacobi I extract the following:

Miss A. B—— was a tolerably healthy child. Between eleven and twelve developed insufficiency of the internal recti muscles; used glasses for a few months, and occasionally a few years later. Has only recently discarded them. Was the eighth child in a family where only eighteen to twenty-four months intervened between any two births.

Father healthy; lost one sister from epilepsy. Mother healthy and of a long-lived family. The brothers and sisters were all more or less delicate; one sister has insufficiency of the internal recti muscles.

Patient menstruated at fourteen; was extremely irregular until twenty; was subject to nervous and sick headaches. At the age of twenty, the first attempt was made to re-establish menses by leeches to cervix uteri. This was successfully accomplished in May, 1879, and continued regularly throughout the summer. In September, 1879, patient, being in the mountains, sprained her foot. Sprain supposed to be slight, but two months later attempt at walking continued to cause great pain. Patient remained confined to her room for eight months without setting the foot to the ground. During this time occasional paroxysms of neuralgiform pain in foot, radiating from inner border near scaphoid metatarsal articulation. Pressure at this point always extremely painful. Conviction gradually entertained that patient was suffering from an hysterical arthralgia supervening on a sprain which had merely been an exciting cause. It was, nevertheless, impossible to induce patient, though a very sensible girl, to use the foot, for each attempt was followed by pain often extremely severe. The general health of the patient was perfect—the first time that this had been the case since the age of twelve.

In the spring of 1880 Dr. Shaffer was asked to see her. He noted the marked malposition of the foot and partial extension and adduction, and attributed the pain to the retraction of the plantar fascia. Dr. Shaffer advised the use of a mechanical shoe, which should gradually stretch the fascia, and recommended that the patient commence to walk at once. This she did with marked relief. She went to Europe, and walked well. While there she heard news which produced quite a profound shock, and various hysterical symptoms manifested themselves. After a varied experience she returned to her home and is now quite well.

Throughout Dr. Jacobi's notes there are various comments upon the hysterical elements as presented by the patient. These I recognized when I examined the patient, and I gave them their full value. I am sure Dr. Jacobi quite agrees with me in attributing the condition of the patient at the time of our consultation to the retracted plantar fascia and shortened gastrocnemius, which rendered the foot very vulnerable. The sprain, which was slight, occurred in a foot which was in a condition of non-deforming equinus. The hysterical condition of the patient only added to the difficulties of the diagnosis and obscured the real condition. On February 20th, of this year, we again met in consultation and found our patient was still suffering from a shortened plantar fascia and gastrocnemius. Tested in standing position the patient could not flex the ankle joint. She has a true non-deforming club foot, with the danger before her, as has frequently happened, of sprains and trouble at the ankle upon slight provocation.

The case is also very instructive as showing how very vulnerable a joint and foot may become with slight contractures, and how long a person may be disabled by a sprain under these circumstances. The pain produced in these cases is sometimes very severe. In a neurotic girl, such as Miss B—— certainly was, the pain was very greatly exaggerated.

In this case there are none of the ordinary causes which can be relied upon to account for the conditions found at the ankle-joint and tarsus. There is no history which furnishes any clue. It does not come under any of the previous classifications. There is no evidence of a spinal cord lesion; nor is there any evidence of a local peripheral lesion. The contracture exists; it is permanent, and it failed to yield under an anæsthetic. Hence we may safely assume that it was not hysterical, however much the hysterical diatheses may have exaggerated the symptoms.

On December 9, 1881, I was consulted by Miss C——. She came to ask my opinion regarding her right foot and ankle. She experienced great pain in walking, and was frequently actually disabled by the pain, which was principally located at the scaphoid bone and in the plantar tissues. The extent of her walking was only one or two blocks. Her exercise was consequently very limited, and she spent most of her time when out-of-doors in her carriage. She was very liable to sprain her ankle upon slight provocation, and after one of these sprains would frequently spend a month upon her couch. She was in excellent general health, and was, when her ankle would permit, a keen enjoyer of out-door sports. There was nothing in a hereditary sense that indicated any trouble, nor was the early history of the patient sug-

gestive, save that she always remembered having had a peculiar walk from about fifteen years of age; and that while her ankle had troubled her, she did not experience any serious inconvenience, except during the three years prior to the time she consulted me.

Upon inspection of the foot there was nothing in its appearance to account for the trouble. There was nothing to indicate any articular inflammation. A high instep was noticeable, and the dorsal surface of the toes and the ball of the foot were disfigured by corns. There was only one point of tenderness on pressure and that was at the scaphoid bone. The plantar tissues were also very sensitive. The calf was large and well shaped, and the muscles were firm and solid. Upon comparing the afflicted member with its mate no gross differences were perceptible. Both feet, dropping into gentle extension as the patient sat upon a high office-chair, seemed normal. The patient informed me that the shoemaker made her right shoe upon a special last, as the instep was higher and the foot slightly shorter. The limbs were approximately of the same length; and the measurement of the calves showed that the right was slightly smaller than the left—one-eighth of an inch.

The presence of corns led me to suggest that she had been wearing tight shoes. She informed me that she had spent "nearly a fortune" in shoes and upon chiropodists. She could not wear high-heeled boots; she had tried them, and they gave her extreme pain. She had consulted several surgeons in this city and in Europe, and nearly all had accused her of high heels and tight shoes, and some had prescribed a particular shoemaker, but she had obtained no relief. I saw by the tone and manner of my patient I had better give up that line of investigation.

In examining further still with the feet in extension, as the patient sat before me, I found another tender point just anterior to the external malleolus. There was neither heat nor redness, however, and she was unaware that tenderness existed at that point until I discovered it. I began to think the patient might be hysterical. But further investigation led me to discard this as wholly untenable.

Pursuing my investigation further, I commenced to test the ankle joints as to mobility. I recalled Dr. M. P. Jacobi's case, and asked the patient to attempt voluntary flexion in the standing posture. She was entirely unable to flex the right ankle; the left one was normally flexible. In attempting to flex the right ankle, the "ball of the foot" remained as if glued to the floor. Strong manual effort on my part, with the patient in the recumbent position, failed to accomplish flexion beyond 90°. The plantar tissues were tense; the foot by actual measurement was three-eighths of an inch shorter than its mate, the test being made in the standing position, tracing the outline of the feet carefully upon paper.

The main difficulty in recognizing this condition, as in all similar conditions, arose from the fact that the examination was made with the patient in the sitting position; which means practically with the feet in the equinus position. It was only when joint motion was fully tested that the real cause was apparent.

The young lady had very strong muscles: on the affected side, the muscles seemed almost too strong to think of anything save tenotomy as a remedy. But I had succeeded in lenghtening the gastrocnemius one and a half inch with the extension shoe, in a case of equino-varus occurring in my service at St. Luke's Hospital, in a boy of sixteen, and I advised the patient to permit a trial of the extension shoe before we resorted to any operative procedure. She consented. One week later I applied the traction force with my apparatus. The first application, though painful, gave great relief. Twenty applications, covering six weeks in time, gave perfect relief, and there has been no return of the trouble. Ankle-joint flexion, though not normal, is sufficient to enable the patient to walk comfortably and without pain, and by this process the foot was lengthened three-eighths of an inch. The plantar tissues yielded as well as the tough gastrocnemius.

I might add to these cases if necessary. Time does not permit their recital, however, and I must pass on to consider a subdivision of this class, having, I believe, the same etiology as the foregoing where the conditions are somewhat different.

6. Non-deforming club-foot found in adults, especially with almost normal gastrocnemius action, but with shortened plantar tissues producing principally a changed relation of the metatarsal bones.

In two cases of this class that I have seen there was a loss of power in the tibialis anticus muscle. Most frequently there is no loss of power at all, and the muscles all respond normally to the faradic tests.

Mis N——, aged twenty-one years, a resident of New York City, came to me in October, 1884, with a letter of introduction from Dr. N. A. Roberts, of this city.

The patient's hereditary history presented nothing that would be likely to throw light upon our subject. There was no history of rheumatism or gout in the family, nor did the patient have any evidence of trouble of this nature.

She could assign no cause for her trouble. When about fourteen she commenced to have pain in her foot. This was soon followed by a swelling at the "big-toe joint." The pain and swelling increased, and she was soon confined to the house, and was unable to walk for months. She consulted several physicians, who ascribed her trouble to one of three causes, viz.: gout, rheumatism, or tight shoes with high heels. Under advice she took much medicine, and went repeatedly to different shoemakers and chiropodists. No permanent relief followed. The tranmatism occasioned by even a short walk brought back her disability. Her general health began to suffer as a consequence of her inability to take exercise.

Her condition when I saw her was as follows: There was a very considerable enlargement at the junction of the first metatarsal bone with its phalanx, which was painful to the slightest touch. The skin was very red and tense. There was no particular pain or tenderness elsewhere. The patient was not at all apprehensive regarding the parts, except as pain was inflicted by pressure. Upon examining the ankle-joint I found that normal flexion was impossible. The foot could be flexed only to a right angle. But there was only slight gastrocnemius resistance. The real resistance existed in a markedly shortened plantar fascia, which rendered the metatarsal bones more vertical than normal. There was no atrophy present, and the muscle responded normally to the faradic current. The patient walked with difficulty and with pain.

The first application of the extension shoe gave great relief. The foot was lengthened one-quarter inch by the first application. After the second application of the traction force there was complete relief, and the patient now considers herself well; though the traction is kept up occasionally.

Mrs. M—— was sent to me on November 24, 1884, by Dr. E. C. Seguin. Dr. Seguin, in his letter of introduction, states that after a very careful examination he could exclude any constitutional cause as contributing to the condition presented by the patient.

The history of the patient shows that there was no perceptible hereditary influence at work. She had suffered during childhood from only two diseases, viz.: pertussis and rubeola. At fifteen she was fully matured, and had been well all her life.

At an early age it was noticed that she had a peculiar walk. As a little girl her friends used to comment upon it, and the patient remembers that her ankles when she was a child gave her more or less trouble. At eighteen years of age her feet became more troublesome, and as she advanced in life they became still more so. She never wore tight shoes or high heels. About three years ago the "big-toe joint" on either foot became

very troublesome. Pain was experienced at that point with a "cramped feeling" at the plantar arch. Walking became very irksome. The patient says she was conscious of restraint, though she could not tell why. The "big-toe joint" became more prominent and more inflamed. Last autumn she became so disabled that she could not walk over one block without suffering very severe pain. Chiropodists were consulted, with temporary relief, and different shoemakers were tried, with uniform disappointment.

The conditions found upon examination were so like those recorded in the preceding case that repetition seems unnecessary. The slightly shortened gastrocnemii, with the very tense and contracted plantar tissues, made the distal ends of the first and second metatarsal bones, the point where much of the weight of the body fell during the act of walking, more vertical than normal. In this instance both feet were affected.

After the second application of the extension-shoe, the relief was very marked. Traction alone had made the foot very perceptibly longer and narrower, and the patient enjoys to-day entire immunity from her "gouty big-toe joints."

Further duplication of this class of cases seems unnecessary. One word regarding "gout." I have seen nine cases of non-deforming club-foot where the principal trouble has been at the "big-toe joints," the favorite seat of gouty pain and swellings. In almost every case, except the last one (Dr. Seguin's), gout or rheumatism has been diagnosticated by prominent medical men. The removal of all unfavorable symptoms by traction proves one of two things: either these were true cases of gout which were relieved, as to the foot symptoms, by the means used, or they were pseudo-gout caused by abnormal pressure upon the exposed articular surfaces. I think it likely that, in some cases, both elements were at work, and that the elongation of the foot, coupled with the new articular relations thereby resulting, has contributed to the result. I am even led by my experience to say that many cases of true chronic gout at the point mentioned may be greatly relieved by the means employed in these recorded cases.

One word, however, before closing my remarks. The celebrated mare Maud S. presents almost the same condition that I have attempted to describe as occurring in the adult and adolescent. From a recent issue of the New York *Tribune* I copy the following remarks, made by Mr. Bonner in describing the present condition of this celebrated trotter. He says, after some general remarks: "You will observe that only the imprint of her toes is visible. The heels scarcely touch the ground. She is literally walking on her toes." . . . "Maud S. has been troubled with severe corns." Mr. Bonner, in a long and scientific way, dwells upon these and other defects in his mare and prescribes for her condition. It seemed to me worth while to stop a moment and notice this very accurate description of the condition I have called to your attention, though applied to a horse rather than to the human being, especially so as my search for medical facts bearing on the subject has been fruitless. And yet there are many persons to-day who are practically walking on their toes, and who, like Maud S., have corns and other disagreeable sequelæ which, I am happy to say, are very easily relieved.

Early Ovariotomies.—In Professor William Gibson's entertaining and instructive "Rambles in Europe in 1839," page 27, we read: "After several hours spent in St. Bartholomew's Hospital wards, Mr. Lawrence took me to the museum, . . . where I saw a great variety of beautiful preparations, many of them put up by Mr. Paget, who is represented as a young man of uncommon talent and promise, and by him I was shown three or four remarkable specimens of ovarian cysts, removed successfully through a small opening into the abdomen."

SUPERFLUOUS HAIR.

The Russian Dog-faced Boy, and Facial Hirsuties in Women.

By GEORGE THOMAS JACKSON, M.D.,

Instructor in Dermatology to the New York Polyclinic, and Assistant Physician to the New York Skin and Cancer Hospital.

By hypertrichosis, hirsuties, or superfluous hair is meant a growth of hair which is either abnormal in amount or occurs in abnormal situations. While it is normal for a man to have a beard of from say four to six inches in length, it would be abnormal for him to have one reaching to his feet. Again, while normally the hair grows thick and strong upon the cheeks, chin, and upper lip of the human male after puberty, should such a growth occur upon the face of the human female it would be abnormal. In most books treating of the hair an abnormality of direction of hair growth is included in the chapter on hypertrichosis. This malady is called *trichiasis*, and is most frequent and most grave in its effects among the eyelashes, the misdirected hair growing toward the conjunctiva bulbi, and causing great annoyance and mischief by rubbing against that sensitive membrane. It belongs, however, to the domain of the ophthalmologist, and will not be further treated of in this article.

Before proceeding with our subject proper, let us stop for a few moments to consider how the hair grows. The first indications of future hair growth are met with on the face of the fœtus at about the tenth to the twelfth week of its existence, and at successive periods upon the scalp, trunk, arms, and legs, till at about the seventh month they are seen upon the backs of the hands and feet. The hair itself makes its appearance about one month later, and in the same order. The hair, roughly speaking, may be said to consist of a *shaft*, whose lower end is expanded into a bulb-shaped *root*, which rests upon and grows from a *papilla*. About the root is a sheath, called the *root-sheath*, and the whole rests in a pocket called the *hair-follicle*, at the bottom of which is located the papilla. The hair receives its nutriment chiefly from the papilla, but also to no small extent from the root-sheath. But the primitive or embryonal hairs are, as a rule, not permanent. At about the sixth to the eighth month of fœtal life a change begins and is continued after birth. This change consists in a falling out of the primitive hairs, which, as a rule, are pigmented, and in a growth of new pale hairs. If the whole process is completed before birth, which is generally the case, the child presents the usual appearance of having hair only on the head and eyebrows, and this sparse and light-colored. Often, however, the process is not complete at birth, and the child is born with long dark hair on the scalp, or it may be that the body also is more or less covered with hair. This is met with not infrequently upon the forehead, exhibiting very beautifully the manner in which hair grows from centres, to the right and left, the line down the middle of the forehead being plainly seen. In most all cases these long hairs are shed, to be replaced by the permanent hair. This is the change of type between the primitive and permanent hair.

Hypertrichosis may be general or partial, congenital or acquired. Of these the general form, hypertrichosis universalis, is very rare, while the acquired form, or hypertrichosis partialis, is the most frequent and is familiar to every one in the cases of the unfortunate bearded women.

Hypertrichosis universalis is generally congenital as well, and, in spite of its name, does not affect the whole body. Hair never develops, even in this disease, in places in which normally no hair is found. It is not met with, therefore, upon the palms of the hands, the soles of the feet, the backs of the last phalanges of the fingers and toes, the inside of the labia majora, the prepuce, and glans penis. Subjects of this malady are usually born covered more or less thickly with hair, which may be light or dark in color. This continues growing longer, coarser, and

darker till it reaches its full development. As a rule the long hair covering the body is fine, resembling more the hair of the head than of the beard, as is also the case with the hair on the face of these people. It follows a definite direction in growing, and this is away from certain well-defined centres. Thus on the back it grows on each side downward and outward from the spinal column; on the forehead away from the middle line, following the lines of the eyebrows, so also from a line running down the face, etc. With this excessive growth of hair there is usually combined a deficiency of teeth, specially marked in the upper jaw.

These homines pilosi are met with in all quarters of the world. Thus we have records of the Kostroma family from Russia, a father and son. They first attracted notice some twelve years ago, and were described in a number of European medical journals. The father died some four years ago in Paris, and the son is now on exhibition in this country in Barnum's travelling combination show. Nothing is known of the parentage of the father, nor have I found any record of the boy's mother. An excellent likeness of the father is given in the last volume of Ziemssen's "Handbuch der Speciellen Pathologie und Therapie." The special interest in these cases is in the face. The father has already been described; I would here speak of the son, whom recently I have examined. He is said to be sixteen years of age, and looks like a well-developed boy, though somewhat under the average height. He appears to be muscular, and is active and energetic in his actions. He seems intelligent, and certainly showed acuteness in the rapidity and correctness with which he gave me change for a dollar bill when I bought his photograph. He talks Russian with great rapidity, and has picked up some English and German words. His agent says that he is docile, and his health is good. His head is covered with a luxuriant growth of fine, glossy hair of blond color, and some six inches long. This extends further down on the neck than is usual. The scalp is normal, white, and soft. Coming forward, the hair grows well down on the forehead, and then continues over the whole face, though on the face it is finer and lighter in color than on the head. The facial hair does not resemble in texture the usual hair of the beard, even where it grows in the places ordinarily occupied by that growth in men, but is much softer. Upon the upper lip there is a space occupying about the middle third, where the growth is very scanty. Under the eyes the hair also is absent for a space of about half an inch. Otherwise the whole face is covered with long hair, it growing from the inside and outside of the nose and continuing all down the neck. There is also a luxuriant growth of hair from the inside and outside of the ear. Under each eye is a group of three or four black hairs. The hair of the face is some four inches long. Upon the body the most remarkable growth is down the spinal column, where the hair stands out not unlike a horse's mane. The rest of the trunk and the extremities are completely covered with hair, but not very much more so than in not a few other hairy people. The backs of the hands present nothing remarkable. On the body the hair is exceedingly fine and delicate, and more fluffy than that on the head and face. There is a cast in his left eye, and he is near-sighted. He has only five teeth, two upper canine, and two lateral and one middle lower incisor. The alveolar ridges show no sign of there ever having been any more teeth. The teeth he has are badly shaped and discolored. His father is said to have had no teeth till he was seventeen years old, and then only four in the lower and one in the upper jaw. The *London Lancet* in 1873 reported the boy as having four incisor teeth in the lower jaw, so he must have lost one.

Other instances of universal hypertrichosis have been reported. Thus the case of Barbara Ursler is cited by Stricker (*Virchow's Archiv*, 1877, lxxi., 111) as occurring in the seventeenth century. This woman's whole body was covered with blond, soft, curly hair, and she had a thick beard reaching to her girdle. In a book published in 1642 and entitled "Aldrovandi Monstrorum Historia," is an account of a hairy family consisting of the father aged forty, a son aged twenty, and two daughters aged eight and twelve. They came from the Canary Islands, and were covered with hair, excepting in the daughters, whose lips, nose, neck, breast, and hands were smooth. In the *Lancet* of 1851, Chowne reports a case of universal hirsuties occurring in a Swiss woman twenty years of age. Her body was covered with hair excepting on the breasts and chest, which were free of the growth. In Beigel's book on "The Human Hair," accounts of several cases of this deformity are given, viz.: that of Julia Pastrana, a Spanish dancer; and of Shewe Maon and his daughter Maphoon, in India. The latter's second child was hairy like its mother. In the father and daughter there was an absence of the canine and molar teeth. But it is useless to multiply examples, as the foregoing cases are sufficient.

Of *partial congenital hypertrichosis* we have an immense number of examples. This condition is apt to be of the nature of nævus. It must be held in mind that the distinction between a localized hypertrichosis and a nævus is made mostly upon the color of the underlying skin. In the former case the skin is perfectly normal, while in the latter it is pigmented and may be otherwise altered. Thus we have in the *Lancet* of 1869, ii., 276, an account of a Mexican woman who had a nævus pilosus extending, like a pair of bathing trowsers, from the umbilicus anteriorly and the sixth dorsal vertebra posteriorly, to about half-way down the thighs, covering the buttocks. Dr. Cummin (*London Medical Gazette*, 1836, xix., 263) mentions the case of a lady who was noted for the beauty of her face, whose body from breast to knee was covered with a profusion of black, thick, bristly hair. Waldeyer ("Atlas der mensch. u. thierisch. Haare") reports the case of a girl nine years of age, who had a lock of hair running from the first to the fourth lumbar vertebra, and a smaller one from the third to the fourth cervical vertebra. These localized and partial cases of hypertrichosis are most frequently met with in the sacral or lumbar region, and not infrequently are associated with spina bifida.

Partial acquired hypertrichosis is more common than is the congenital variety, and takes the form either of an excessive growth of hair in regions where it is usually found, or of the development of hair in regions usually hairless or only provided with downy or lanugo hair.

The following cases are instances of excessive growth and precocious development. Chowne (*Lancet*, 1852, i., 421) speaks of a boy eight years of age, who had the whiskers of a man. Beigel (*Virchow's Archiv*, 1868, xliv., 418) has seen a six year old girl with pudenda like a twenty year old woman, both in shape and hair. As cases of excessive growth, the following may be mentioned: Leonard ("The Hair, its Diseases and Treatment") mentions the case of a man in his neighborhood whose beard measured seven feet six and a half inches in length. Other instances of excessive length of beard are met with in medical literature, such as that of the carpenter at Eidam, whose beard was nine feet long, and who was accustomed to carry it in a pocket devoted to the purpose; and that of the Bürgermeister of Braunau, whose beard reached to the ground. Wilson met with a lady who was five feet five inches in height, whose hair, when she walked, trailed three or four inches on the floor. Many men have an excess of hair upon the chest and shoulders. Hair is generally better developed upon the forearm than upon the upper arm, and upon the legs than upon the thighs. As men grow old they are apt to have long hair grow from the nostrils and the ears. These are instances of the growth of strong hair where normally only lanugo hairs are present. But these cases are interesting as curiosities, and as subjects of study. The growth of the beard in women is the form of hypertrichosis which concerns us most, as it is the deformity

which we will be called upon to cure. As women grow old, especially after they have passed through the climacteric period of middle life, a slight mustache or a few straggling dark hairs on other parts of the face often appear. These growths seldom annoy them much, as they are accepted as evidences of advancing years. The case is very different when a young woman is afflicted with a beard, and most of the patients who apply for relief from their facial hair are between twenty and thirty-five years old. The hair generally begins to grow so as to be noticeable at about the eighteenth year of age. To get rid of the trouble the tweezers are first resorted to, and this only makes matters worse. Then depilatories are tried which have but a passing effect, and some of them leave bad scars. Sometimes burning is attempted, and as a final refuge the razor is used. All the time the hair grows coarser and more abundant. Were this all, though it would be bad enough, these cases would not so greatly need our aid. The deformity is only the beginning of evils. These women shun company, keep themselves shut up all day, their health deteriorates, and constantly brooding over their misfortune, they are prone to become hypochondriacal and melancholic. Any one devoted to dermatological practice must have seen these nervous, sensitive women, whose health is broken and spirits depressed on account of, it may be, no very formidable facial hirsuties. The amount of hair presented by these cases varies. Perhaps the commonest growth is a mustache alone. In most of my cases the hair has grown thickest and coarsest under the chin and upon the front of the throat. It is rare, even in the best developed cases, to have much hair under the lower lip. Sometimes the growth is as complete, as heavy, and as coarse as is met with in men; an excellent account of such a case is described by Duhring in the *Archives of Dermatology* for 1877, p. 193 et seq. The skin of many of my cases has been coarse, muddy, greasy, and studded with acne.

From time to time cases of transitory hypertrichosis have been reported. This has been noticed during the treatment of a fractured limb, the hair being much more prominent upon the part that has been kept quiet and warm. In some of these cases the increase is probably more apparent than real, the hair not having been rubbed off by friction. Likewise, after injury to nerves the hair sometimes becomes hypertrophied, only to fall off after recovery. Continued irritation of a part, as by blisters, may stimulate hair growth which may or may not be transitory. The most interesting of this group of cases is that comprising those of hirsuties occurring during pregnancy, and disappearing again after some months. Wilson reported a case of delayed appearance of menstruation in which hair grew upon the face. After the menstrual function was established, the hair ceased to grow and gradually fell off.

The cause of hypertrichosis is very obscure in some of its forms, while in other varieties we can more readily discover it. In universal hirsuties heredity plays an important part. Such instances as those of the Kostroma, father and son; of Shewe Maon, and his daughter and grandchild, and others like them, attest this fact. But hereditary tendencies will not explain the first appearance of these congenital cases. Virchow endeavored to account for them upon the theory of nervous influence, founded upon the fact that in the Kostroma people the lack of development of the teeth and jaws was in the same zone as the over-development of the hair on the forehead, nose, cheek, and ears; these regions all being supplied by branches of the trigeminus or fifth cranial nerve. A glance at the account of the growth of the hair at the beginning of this paper, which is taken from Unna's article on the anatomy of the skin in the last volume of Ziemssen, will, I think, furnish good grounds for accepting his theory of congenital hypertrichosis, viz.: that it is due to a persistence of the fœtal or primitive hair; the change of type between the primitive and permanent hair not taking place. At the present time it is hardly necessary for us to gravely discuss the theories of maternal impressions, fecundation of the human female by a hairy animal, and the like.

The cause of acquired hirsuties is, in some cases, not far to seek. Heat and moisture will apparently increase the growth of hair, just as they favor the growth of vegetable life. Thus the hair has grown luxuriantly under the stimulation of poultices, and on the limbs when confined in a fracture-box. To these factors must be added an increase of the flow of blood to the part. Increase of the flow of blood will stimulate hair growth independently of heat and moisture. At least Prentiss' case of hair growing more luxuriantly and coarser under the use of pilocarpin, which causes hyperæmia of the skin, would seem to indicate this. Hypertrichosis following injury to nerves is probably dependent upon vaso-motor disturbances. The growth of hair upon exposed parts, as upon the arms and chest of laboring men, sailors, and the like, is due to the local irritation of the sun and wind.

Now we come to the more obscure cause of facial hirsuties in women. To account for this numerous hypotheses have been formed. Probably the one most generally accepted is that it is in some way connected with derangement of the uterus and appendages. Because in some bearded women there has been some evident derangement of the sexual organs, it has been affirmed that some similar derangement is present in all. This is on a par with the too loosely accepted idea that too free use of alcohol is the only cause of rosacea. In the cases I have met with, the majority were as free from uterine trouble as the rest of their sex. While it is true that some of these women are of masculine build, and have a masculine voice, most of them do not exhibit these characteristics. The heaviest bearded of my female patients was the mother of three children, and this experience is not unique. In some cases, however, there does seem to be some relation between the reproductive organs and the growth of the beard. Several instances illustrative of this have been given above. Recently, I have met with a case of a woman with a dark but not very heavy beard, which began to grow about one month before the birth of her fourth child. Then the appearance of hair on the face of women who have ceased to menstruate would suggest such relationship. We may sum up the evidence on the etiology of facial hirsuties in this way: While at times there appears to be a relation between the uterine, or more properly, the menstrual function, and the growth of hair on the face, shown by a decrease or deficiency of the first, and an increase of the second, still in the majority of cases no such relation is discoverable, and it must be viewed as a deformity or freak of nature.

An interesting study of the relation between hirsuties in women and insanity was made by Hamilton (THE MEDICAL RECORD, 1881, xix., 281). He regards hair growth on the face in women as the inevitable result of the over-active and continuous exercise of the uterine and ovarian functions. He believes it to be of neuropathic origin, connected with disorders of the fifth cranial nerve; and that when it occurs upon the face of an insane person it is indicative of an unfavorable form of insanity, especially if the subject had not reached middle life.

The *treatment* of hypertrichosis is simple and efficacious, though laborious and tedious. For general hypertrichosis we can practically do nothing. This, not because we cannot destroy hair so that it will not grow again, but because of the great amount of time it would take to destroy it. Happily, a superfluity of hair on the body does not incommode the bearer of it, nor, in most cases, do him any damage. One case, however, is upon record where the consequence of too much hair resulted in serious damage. We read of a woman in old times whose face was very beautiful. She made an advantageous marriage, but the husband was disgusted to find her body covered from breast to thighs with a profuse growth

of stiff coarse hair. Upon the strength of this he was divorced from her on the next day.

The only form of hirsuties which urgently calls for relief is that occurring upon the face in women. Until recently there was no cure for this, but in 1879 Dr. Michel, of St. Louis, devised the method of removing the hairs in trichiasis by means of electrolysis, which was taken up by Dr. Hardaway, of the same city, for the removal of superfluous hair. Since then the art has been practised by a number of physicians, notably by Dr. George Henry Fox, of this city. The question is often asked: "Is the removal, by this method, permanent?" This question may be answered, "It is, without a shadow of a doubt." The object being to destroy the papilla, and that being very small and often placed at an unexpected angle to the surface of the skin, it is not possible always to accomplish this at the first attempt. The amount of success on going over the face the first time will vary with the operator, and, according to his skill, there will be a return of from twenty to fifty per cent. of the hairs removed. It will be necessary, therefore, to go over the face a second or a third time, but then there will be no return. At times, after the dark coarse hairs have been removed, there will be found a number of finer and lighter hairs. This appearance is due partly to the uncovering of these hairs and, partly it may be, to lanugo hairs becoming stronger under the stimulation of the operation. In most cases, with proper care and the use of a fine needle, the amount of scarring will be very slight, amounting to nothing more than fine punctate cicatricial spots. In some peculiarly irritable skins it is very difficult to prevent the formation of plainly visible scars. If the proper conditions are not observed, the operator must expect to produce a good deal of disfigurement.

The amount of pain experienced by the patient will vary greatly. Some women will complain bitterly of a current of half the strength that other women will bear with ease. Certain parts of the face are far more sensitive than others. The most sensitive points, I have found, are over the ridge of the lower jaw on each side of the chin, and about the upper lip. On the whole, the pain does not amount to much, and if it does, I have found that it may be greatly lessened by rubbing the oleate of cocaine into the skin for some five or ten minutes before beginning the operation. After a time the skin seems to become tolerant of the action of the current and the patient no longer complains. Hyperpigmentation may be produced by the operation. This is a very rare complication, and is only mentioned by way of warning. I have seen it in only one case, a hypochondriacal woman, and here, instead of the redness which is always produced about the point of puncture, fading away in a few days, it gave place to a dark brown stain which remained for a number of months.

The instruments needed for the operation are a good twenty cell zinc-carbon (galvanic) battery, a sponge electrode, a proper needle-holder, a fine needle, a pair of epilating forceps, and, if the operator's eyes are not good, a lens of low power. The battery which I have been using for the past year, and which has given me great satisfaction, was made by Messrs. Waite & Bartlett, 204 East Twenty-third Street, of this city. Its current is even, and it is exceedingly easy to keep in order and to manage. Any sponge electrode will answer. There are various patterns of needle-holders, any one of which may be used. I prefer one which is not longer than three or three and a fourth inches, with a diameter of about three-sixteenths of an inch. It should be long enough to be held with ease, and not too long to be readily manipulated. If the woman has a large bust, a high chest, and a short neck, a short holder will be found a great convenience when working under the chin. The most essential instrument is the needle, and for the best success this must be carefully chosen. At first the finest cambric needle was used, and it did fairly well. Dr. Hardaway, in the April number of the *Journal of Cutaneous and Venereal Diseases*, speaks of a needle which recently he has had made, of iridium and platinum. He claims that it will follow the direction of the hair follicle, and more surely hit the papilla than will a steel needle. I have had most satisfactory results with a jeweller's instrument called a "steel broach." These may be had of any dealer in jewellers' supplies. Mine I obtained from Messrs. L. H. Keller & Co., 64 Nassau Street, in this city. These come in many grades; that known as No. 3 is a serviceable one. Their cost is trifling—a few cents a dozen. I would recommend care in selecting them, as they are so fine that their points are sometimes broken while in the packages. A lens is generally not needed. Dr. Piffard has invented a needle-holder with lens attachment, which he has found useful.

A good light is necessary for the operation, and a cloudy day is a bad one for working. An operating or reclining chair is a comfort, and the patient should be so placed that the part to be operated on is on a level with the operator's eye. The operation is done in the following manner: The patient, being in position, is to be given the sponge electrode attached to the positive pole of the battery, and told to hold it in one hand. The hair to be extracted is then seized with the forceps, and put slightly on the stretch *in the direction in which it naturally grows*. The needle, attached to the *negative pole* and held like a pen-holder, is then inserted parallel with the hair and into the follicle. One soon learns to know whether the follicle is entered or not by the sense of touch. When the follicle is entered the needle glides along smoothly; when it is not entered a sense of resistance is communicated to the fingers as the skin is punctured. The depth to which the needle is to be thrust will vary with the case. Roughly speaking, it is from one-sixteenth to three-sixteenths of an inch. The needle being inserted, the patient is told to place the palm of the disengaged hand over the sponge electrode. Watching the effect on the skin, a slight hyperæmia will be noticed about the point of insertion of the needle, which almost instantly gives place to a blanching of the tissues. In a few moments there will be frothing about the needle, and in from half a minute to a minute or more, the hair will come away upon *the very slightest traction*.

Such is the operation. Care must be taken to use the negative pole, for otherwise, instead of an electrolytic action a charring of the tissues will result, and permanent blackish spots will be left in the skin. The hair must not be pulled on with any force, for the ease with which it leaves the follicle is a guarantee of the completeness of the operation. The hairs must not be extracted in close proximity, because the inflammatory action thus set up will lead to more or less deep ulceration and subsequent prominent scars. At first, at least, some three-sixteenths of an inch should be left between the hairs; later, when the susceptibility of the skin is known, they may be taken out nearer to each other. It is best only to extract the coarser hair and to leave the lanugo hairs alone. The strength of the current to be used will depend upon the quality of the patient's skin and the recentness of the filling of the battery. Eight cells are the fewest I have used, and fifteen the greatest number.

The immediate effect of the operation is the production of a number of wheals. On the next day only red points are seen, and in a few days the skin shows minute cicatricial points, but only when examined with the greatest care. The finer the needle is, the less the reaction will be. The patient should be directed to bathe the face in *hot* water and to anoint it with cold cream.

If these directions are carefully carried out, and the requisite skill in the introduction of the needle is acquired by practice, an absolute cure will be the result.

14 East Thirty-first Street.

The Fever at Plymouth, Pa.—Several new cases of typhoid fever have occurred during the past week.

THE TREATMENT OF ACUTE RHINITIS.

By J. M. W. KITCHEN, M.D.,
NEW YORK.

It is to be supposed that most practitioners have felt with the writer their lack of power in being able to control an ordinary "cold in the head." Many will say that it is impossible to cut short such an attack—that it must run its course of from three to ten days. Even so eminent an authority as Morell Mackenzie states that if the attack has lasted for two or three days it is hopeless to abridge its course. I cannot agree with this opinion, because my experience has shown that it can be done. Very few patients think it desirable to apply for treatment for so self-limited a disorder as an attack of acute rhinitis; and yet in most cases, if the patient will submit to the necessary restraints of treatment, the attack, if not aborted, may generally be restricted to at least one-third of the time of its natural duration; and in any case, the discomforts of the attack may be greatly alleviated.

Predisposition to such attacks may be much decreased by surgical correction of abnormalities in the structure of the nasal cavities; by the adoption of better hygienic habits and practices calculated to improve the general nutrition; and by invigorating exposures to hardening influences, which include regular out-of-door exercise, cold sponge-baths, and breathing cool, pure air indoors. This latter requisition necessitates the use of the open grate fire, and sleeping in a cool, well-ventilated room having a temperature in the winter season of about 50° to 60° F. Very cold sleeping apartments are not desirable.

Acute rhinitis may be frequently *aborted*. If taken in time, a large dose of alcohol or other medicament producing flushing of the general peripheral surfaces of the body will frequently be found effective. A full dose of opium or other general sedative will also usually suffice to prevent the attack. But the practitioner rarely meets a case for treatment, outside of his immediate family, that is not already fairly started in its course. A speaker or singer may be the applicant, and wants relief so that professional duties may be acceptably performed in a few hours. What, then, should be done for such cases? These patients will usually submit cheerfully to the necessary treatment. The indications to fulfil are as follows: To quiet the circulation by means of aconite and absolute muscular repose; to soothe the general system with sedatives; to avoid reflex influences by remaining quietly in a recumbent position in a moderately warm apartment, well protected by sufficient covering; and to seek the advantages of derivation by heat applied to the feet, the other parts of the body being also kept warm while the nose is kept continually cool by external applications. This can be conveniently done by placing a small, thin rubber bag of cool water across the bridge of the nose for several hours. The water should not be so cold as to be painful. Cold sponging of the nose and inter-orbital space is good, but not so desirable as the other method. Lastly, frequent intranasal mild astringent and sedative applications may be made; and in carrying out this procedure in past times the chances were that the inflammatory action would be aggravated.

It is almost impossible to make an application in these cases with a spray or insufflated powder, without irritating the already inflamed swollen tissues, or to make an application to the whole of the inflamed surfaces, because of the occlusive tumefaction. If the spray is used, the anterior portions of the turbinated tissue receive the forcible impact of most of the application, and are much irritated; while if a powder is insufflated, though it requires an air-current of slight force to carry it into the cavities, in almost all cases it acts as an irritant. Liquid medicaments are less irritating than powders, after the application is made. Furthermore, another difficulty in properly medicating the nasal mucous membrane arises from the presence of the large amount of blood contained in the sponge-like erectile tissue in its inflamed state — blood which seems to dilute and make impotent such applied medicament as may haev been deposited on the disordered membrane. To overcome these difficulties, the writer has devised a very simple and satisfactory nasal bather for making applications to the nasal cavities. It is in no sense a nasal douche. If a beneficial application is to be made in these cases, it has to be done in the most gentle and guarded manner. To effect this purpose the bather (see Fig. 1) is constructed so that the fluid used can only flow

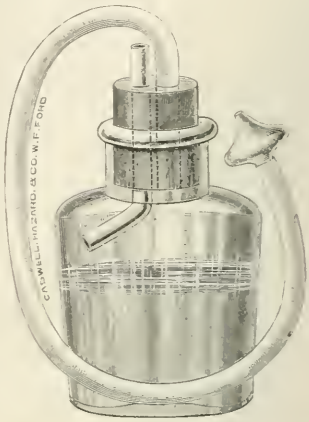

FIG. 1.

from the bottle in a very gentle current, and at a very low hydrostatic pressure.

Fig. 2 shows the method of application. The nose-piece is held tightly to the nostril, and the bottle raised the few inches allowed by the length of the flexible rubber tube, care being taken to keep the bent glass air-duct at the top, so that the liquid will only escape through the outlet. The bathing fluid then slowly flows from the

FIG. 2.

bottle and insinuates itself gently over all the surfaces of the mucous membrane in such quantity that even mild unirritating solutions if allowed to remain for some moments, produce a decidedly satisfactory effect, and with great economy as to the amount of solution used. Of course even ordinary functional use of the nose should be discontinued during the treatment, and violent blowing of the nose, or snorting, or forced inspiratory or expiratory blasts through its cavities should be avoided. Steam inhalations in these cases, though comforting, are not curative. General diaphoresis does more harm than good in the average case. Cocaine is also undesirable. It is

anæsthetic and constringing, but its appllcation is followed by an irritable reaction. I have found a very mild solution of alum and morphia with cherry-laurel water, to act best.

After the more acute symptoms subside, stronger solutions may be used in the bather.

This simple little device will be found of great service in the palliative treatment of hay fever. It is hoped, though, that the general public may be soon so thoroughly alive to the advantages of a skilful application of the galvano-cautery knife to the irritable parts of the nasal mucous membrane, that mere palliative measures will very seldom be called for in the treatment of that disorder.

Progress of Medical Science.

The Operative Treatment of Knock-knee.—In a communication addressed to the Società di Chirurgia Italiana, and published as a reprint from the *Archivio e Atti della Società*, Dr. Pietro Panzeri gives the results obtained by him in upward of four hundred operations for the relief of genu valgum. In his first operations he followed Chiene's method of removing a wedge-shaped piece from the femur just above the internal condyle. This answered well in the case of children, but in a young man, twenty-one years of age, upon whom it was practised, the internal condyle was broken off, and the patient died from subsequent septicæmia. After this experience Dr. Panzeri abandoned Chiene's operation and adopted Macewen's in the case of adolescents. For children he had recourse to *redressement forcé*, and even employed this method frequently in the treatment of knock-knee in adolescents, contrary to the usual practice. He operated in this manner in more that three hundred cases, and expresses himself as thoroughly satisfied with the results. Many, if not most, of these cases would no doubt have recovered in time if provided with the ordinary mechanical supports, but the author believes that, taking into consideration the ignorance and carelessness of dispensary patients, it is the wiser plan to resort at once to forcible reduction. The operation, he states, almost always excited a moderate amount of reaction in the knee; in four cases the inflammation was severe, but all resulted in recovery. The writer never met with excessive lateral mobility of the articulation as a consequence of *redressement forcé*. A few relapses were noted, but they were confined to those cases which had been operated upon prior to the age of six years, and never reached a degree as great as that of the original deformity. In six adolescent cases paralysis of the peroneal nerve occurred as a result, the author thinks, of pressure from the retention apparatus applied after redressement. The patients treated by this method were able to walk without supports in from two to three months after the operation.

Fracture of the Patella.—Dr. Delbastaille reports a case of fractured patella successfully treated by silver-wire sutures. In forty-eight days after the receipt of the injury the patient was allowed to walk with the aid of a cane. The sutures became encysted, and caused no inconvenience.—*Annales de la Société Médico-Chirurgicale de Liége*, No. 2, 1885.

Sprain of the Superior Tibio-fibular Articulation.—Dr. Bouilly relates the following case in the *Annales Médico-Chirurgicales* for April, 1885: "A gentleman, sixty years of age, of good muscular development, made a misstep, falling nearly on his knees, but recovering his equilibrium by a violent muscular effort. At the same time he felt severe pain in both knees, but was able to walk to his home. During the following two or three days the pain increased in severity so that the patient was unable to walk about his room. The pain was located, not in the knees, but at a point to the outer side and below the joint over the anterior part of the tibio-fibular articulation. There was slight ecchymosis at this point and also a moderate degree of swelling. The sprain was evidently caused by the violent antagonistic action of the biceps and quadriceps at the time of the accident; the joint being partly flexed, the biceps pulling on the head of the fibula was working at its best advantage, and the violent action of the quadriceps in the effort to prevent a fall excited also a contraction of the biceps, with consequent strain or rupture of some of the ligamentous fibres over the anterior surface of the tibio-fibular articulation."

Cure of Malignant Pustule by Corrosive Sublimate.—The following are the conclusions of Dr. Romei from the observation of a number of cases of this affection (*Gazzetta degli Ospitali*, March 4, 1885): 1, The external employment of corrosive sublimate is almost always successful, provided the disease be not too far advanced; 2, its application is simple and easily made, and is not at all painful; 3, bichloride of mercury does not produce the cicatricial retractions which follow other methods of treatment; 4, its use is preferable to that of the thermo-cautery, since it does not frighten the patient and is painless; furthermore the hot iron leaves an eschar on which the infecting germ may develop; 5, it is a rational method, taking into consideration the infectious nature of the disease and the antiseptic action of the remedy.

Treatment of Typhoid Fever with Large Doses of Bismuth.—Dr. Real treats typhoid fever on the disinfectant plan by giving bismuth in huge doses. He begins by giving an enema containing two and a half drachms of subnitrate of bismuth, and then administers the same remedy internally in doses of five to six drachms per diem. This quantity is divided into twenty-four portions, one of which is given suspended in mucilage every hour. If constipation occur, three or four drachms of sulphate of soda are given either by the mouth or the rectum. The patient is made to drink two to three quarts of milk a day and some Vichy or other effervescing alkaline water, and may also take two pints of beer or one or two ounces of brandy. Of sixty-two patients treated by this method but two died.—*Raccoglitore Medico*, April 10, 1885.

Treatment of Endocarditis.—When endocarditis is found to be present, Dr. C. Paul applies a large blister over the region of the heart, orders rest, and prescribes some cool acidulated drink. If the disease occurs with articular rheumatism and salicylate of soda or sulphate of quinine is found efficacious, its use is continued as long as the pulse is not too rapid and irregular. If, however, the heart's action is disturbed, tincture of digitalis is to be given in doses of twenty drops twice a day, and gradually increased to sixty or eighty drops. The dose should not be increased until two days have elapsed, and as soon as the heart's action becomes regular the remedy may be diminished in quantity or suspended. The tincture of convallaria maialis, in doses of seventy-five minims per diem, may be given in place of the digitalis. As soon as the pulse becomes regular, recourse must be had to tonics, and especially the soluble ferruginous preparations.—*L'Union Médicale*, March 31, 1885.

Milk from an Aged Breast.—Dr. F. H. Nichols, of Atlanta, Ga. (*Atlanta Medical and Surgical Journal*), reports the case of an infant, born just as the mother expired, the womb contracting well while the mother was *in articulo mortis*. This infant was taken and adopted by the grandmother, a woman over sixty years of age, who, to appease its crying, accustomed it to nurse at her dried-up breast. The milk returned. The child thrived, and is now a promising five-year-old boy.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 23, 1885.

THE OPERATIVE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

THE treatment of congenital luxation of the head of the femur is usually, and with justice, regarded as one of the most unsatisfactory tasks with which the surgeon finds himself confronted. Many attempts have been made to devise some method by which the head of the femur could be returned to the acetabulum and maintained in that position until the parts had so adjusted themselves that a permanent cure would result. Perhaps the most promising of these efforts were those of Pravaz, father and son, yet it is very doubtful whether they were actually successful in restoring the head of the femur to its normal place on the ilium. In most, if not all, cases of congenital dislocation, certainly after the lapse of a few years, the cotyloid cavity no longer exists, or at most is merely a shallow depression on the ilium, utterly incapable of holding the femoral head, even could it be drawn into it. Hence it is that patients suffering from this deformity are usually advised to procure a high-soled shoe for the affected side, if the luxation is unilateral, or are told that their trouble is incurable, if it is unfortunately double.

Within a few years, however, some essays looking to the cure of the affection by operative measures have been ventured with results which are certainly very encouraging. E. Rose [1] appears to have been the first to practise resection of the articular end of the femur in a case of congenital dislocation. This he did in 1874, being led to perform the operation by reason of excessive mobility of the joint in a case under his observation. C. Reyher [2] removed the head of the femur in two cases of unilateral luxation, and having freshened the surface of the acetabulum, brought the extremity of the neck into apposition with it, retaining it there by an immovable bandage. At the end of about four months the patients were able to walk. Heusner,[3] of Barmen, reported an interesting case at the Congress of German Naturalists and Physicians, held last year at Magdeburg. The patient was a young woman, twenty years of age, with double congenital dislocation of the hips. She had suffered great pain in the left hip for seven years, and extension by weights and by a hip-splint had brought no relief. Heusner removed the head, neck, and a portion of the shaft of the femur, and, having deepened the cotyloid cavity with the chisel, brought the parts into apposition. At the time that the patient was presented to the Congress, nearly three months after the operation, she was able to walk a considerable distance with the aid of a stick, without fatigue. Margary,[1] of Turin, in a communication presented to the International Congress of Copenhagen, states that he has performed seven exsections of the head of the femur for the relief of this deformity, three for unilateral and four for bilateral dislocations. He opens the joint by means of a straight incision passing from the great trochanter to the posterior superior spine of the ilium, the thigh being adducted and flexed to an angle of 45°. If the capsular ligament is not freely opened by the primary incision, the aperture is enlarged upward by a probe-pointed bistoury, and downward to the upper margin of the neck by a straight resection knife. The round ligament is then divided, and the soft parts being protected by blunt hooks, the head is severed from the neck by an Adams saw. A drainage-tube being inserted, the wound is then closed by sutures and the dressing applied with antiseptic precautions. Immediate extension is then made upon the limb by the weight and pulley, beginning usually with about seven pounds. The results in the two cases which the author reports at length were very good. The patients were able to walk well with the aid of a cane, and in one case, twenty-two months after the operation, the boy had discarded the stick and walked with a scarcely perceptible limp. The deformity was also markedly lessened; the trochanters were no longer prominent, and the lordosis had disappeared. Considerable joint motion was possible.

Another operation which Margary [2] performed in 1882, upon a boy fifteen years old, would seem to be preferable in many cases to exsection, although it was unsuccessful in this instance. It consisted simply in opening the joint through a T-shaped incision, and chiselling out the acetabulum to a depth sufficient to receive a little over half of the head of the femur. The luxation was then reduced and the capsular ligament was strengthened by a strip of periosteum removed from the posterior superior margin of the acetabulum toward the iliac fossa. The patient unfortunately died on the eleventh day, from pyæmia which was caused apparently by septic cat-gut, since suppuration was found to have occurred at each point of suture.

These few cases, while by no means sufficient to place the operation among those of recognized utility, are yet of value as demonstrating the practicability of restoring the obliterated cotyloid cavity and of reforming a useful hip-joint. We shall look with interest for the reports of further trials of coxectomy in congenital dislocation of the hip, and we cannot but hope that the promise thereby held out of relieving the unfortunate subjects of this malformation may be realized to the full. We should then have no more desperate and ludicrous suggestions as that of Mayer,[3] who actually excised a portion of the femur of the normal limb, in a case of unilateral deformity, in order to equalize the length of the two extremities.

DEATH FROM FALLS.

People have been killed by a fall of a dozen feet. Others have fallen from heights of thirty to fifty feet, striking the ground, and have not been seriously injured. It is not possible to say how high a fall must be to be fatal. This is known, however, that children, drunken men, and sleeping men sustain falls and shocks well, owing to the greater elasticity and the more relaxed condition of their tissues.

Jumps and falls into water may be made, it appears, from very great heights without necessary loss of life. Sam Patch jumped safely into the Genesee River from a height of 100 feet. In jumping from a height of 125 feet he lost his life. In 1876, a rope-walker at Niagara Falls dropped from his rope a distance of 130 feet into the river below and successfully repeated the operation a dozen times or more. In 1882, a half-drunken man jumped from High Bridge into the Harlem River, a distance of 145 feet, and was picked up alive. The unfortunate man who lost his life by jumping from Brooklyn Bridge this past week had already, a year or two ago, jumped safely from a height of 110 feet. He had some reason to believe, therefore, that he could perform his last feat with success also.

The prevalent belief that in falling from great heights respiration is stopped and that unconsciousness occurs before the ground or water is reached is not based upon any physiological grounds whatever. The death or the injury, when it occurs, is the result of the concussion. This may not only break bones and rupture internal viscera, but it may bring the heart to an instant rest by acting reflexly upon the vagus. Naturally, the only way to avoid this most serious danger is to have the body strike the water upon an insensitive part like the feet and lower limbs. Jumpers, like Sam Patch and Odlum, kill themselves because they are bunglers, not educating themselves to their feats as circus acrobats do. With some preliminary training a jump from the East River bridge, barring strong winds, need not be fatal. That it is foolish, dangerous, and profitless goes without saying.

THE CONDITION OF GENERAL GRANT.

During the past week, General Grant has been in a comparatively comfortable condition. He obtains his full amount of sleep, takes his nourishment without difficulty, and is quite free from pain. At the consultation, May 17th, Drs. Sands, Shrady, and Douglas being present, it was found that the swelling under the angle of the jaw on the right side had increased in size; that the glands were still indurated and deeply fixed, also that there was a tendency toward diffused infiltration into the adjoining tissues of the upper and anterior portions of the neck. There was consequently some rigidity of the jaws, preventing the wide opening of the mouth, thus in a measure interfering with the examination of the throat. The palatal curtain was somewhat swollen, but the destructive processes at the side of the uvula had not markedly extended. No change had been noted in the appearances of the right tonsillar region, nor in those of the posterior part of the pharynx. The ulceration on the right side of the base of the tongue showed a tendency to extend backward, was more excavated, and had an elevated and indurated border. At the examination on Wednesday, made by Drs. Douglas and Shrady, the local conditions we e found to be unchanged.

SPLENOTOMY, AND THE INDICATIONS FOR ITS EMPLOYMENT.

The experiences of the surgeon and the physiologist in connection with the removal of the spleen have already borne considerable fruit, and we are in a position now to speak quite definitely as to many points bearing on this subject. It was known to the ancients that animals who had by injury been deprived of their spleens might survive, and both Aristotle and Pliny expressed their belief that this organ was not essential to life. Many observers in recent times have confirmed this view.

The careful experiments of Zésas (*Langenbeck's Archiv*, Band xxviii., p. 815, and of Winogradoff (*Wratsch*, 1883, Nos. 6 and 7; *Revue de Chirurgie*, 1885, p. 318) show best the results of extirpation of the spleen in lower animals. Zésas found that in rabbits, after extirpation, there was an increase in the number and the size of white corpuscles, and a diminution in the number and size of the red cells. These changes progressively increased until the tenth week, when they reached their maximum. The mesenteric, and in some cases the subclavicular lymphatic, glands were enlarged. In two cases there was hypertrophy of the liver. Winogradoff found in dogs substantially the same changes as had Zésas, the lymphatic glands being increased in size from sixteen per cent. to twenty-six per cent. of the weight of the animal.

In man the spleen has been removed on account of injuries in 18 reported cases, and on account of diseases in 37 cases, making a total of 55. In the splenotomies for traumatic lesions the patients in all cases recovered. In the operations for disease there have been 29 deaths and 8 recoveries, or about twenty-one per cent. This does not, however, present the matter fairly, as Dr. H. Gilson shows, in a careful review of the subject prepared for the *Revue de Chirurgie* of April 10, 1885. It is probable that many cases in which the spleen has been removed for injury have not been reported. On the other hand, the results of removal of the spleen depend much upon the condition of the diseased organ and of the patient.

The spleen was removed in 2 cases for cysts, in 2 cases for mobility, and in 1 case for lympho-sarcoma, in all 5 cases with success. The spleen has been removed 19 times for leucocythæmia, and with only one successful result, obtained by Franzolini, of Turin, in 1882. It seems, therefore, that leucocythæmia is a contra-indication for splenotomy. The spleen has been removed 12 times for non-leucæmic hypertrophy, with two successes.

The indications for splenotomy, therefore, are traumatisms, wandering spleen, cysts of the spleen, and primary splenic hypertrophy.

Of the patients who have survived after the removal of the spleen, there are histories given of only five. These histories are so imperfect, however, that no positive deductions can be drawn as to the effects upon the human system of the removal of the spleen. There ap-

pear to be sometimes enlargement of the lymphatic glands and of the thyroid body, and there are temporary changes in the number of the blood-cells, such as have been observed in the lower animals.

In performing splenotomy a median incision is preferred. There is no special technique, but the rules governing abdominal surgery must be applied. The great source of danger is from hemorrhage.

In connection with this subject, it will perhaps interest our readers to learn the latest views of the physiology as given by Professor Alex. Tauber, of Warsaw, in a recent number of *Virchow's Archiv*.

The deductions Tauber draws from experiments and from clinical observations are: 1. That the spleen must be regarded as one of the main reservoirs of the blood; its removal therefore exerts a great influence on the circulation, as seen in the occurrence, shortly after the excision, of congestion of the liver, kidneys, and especially of the lymphatic glands. 2. No physiological affinity exists between the thyroid and the spleen. 3. An animal of middle age bears splenotomy much better than an old animal, hemorrhages being liable to occur in the latter. 4. Animals deprived of the spleen can bear living young, in whom the spleen is present. 5. The removal of the spleen does not impair the digestive function or nutrition. 6. After removal of the spleen the animal becomes anæmic; the relative and positive number of white corpuscles notably increases, while the size and number of the red corpuscles diminish.

News of the Week.

The Degree of F.R.C.S.—Dr. G. W. McCaskey, of Fort Wayne, Ind., writes us, referring to a statement made by a correspondent in The Medical Record of March 25th, that he has received the following note from Mr. Henry A. Pitman, Registrar of the Royal College of Surgeons of London. It reads as follows: "Dear Sir: In reply to your letter stating that a degree of F.R.C.S. can be passed in twelve hours by a physician in good standing, I beg leave to inform you that there is no truth whatever in the statement."

An Anti-vivisectionist Disposed of. — Mr. J. Rendel Harris, Associate Professor of New Testament Greek and Paleography, at the Johns Hopkins University, seems, says the correspondent of the *Boston Medical and Surgical Journal*, to have found his field of instruction too restricted, and to have fallen foul of the laboratory work of the biological department. As a consequence, Professor Harris's connection with the university has been severed. He announced that he "would rather resign all advantages of a connection with the university than compromise in the least degree his freedom of speech," which is apparently to be interpreted that he does not care to teach New Testament Greek unless he can preach anti-vivisection. Mr. Harris is said to be of the strictest sect of English anti-vivisectionists.

Cancer and Cigar Smoking.—Tobacconists in this city admit that since publicity was given to General Grant's case, there has been a considerable falling off in the number of cigars sold in this city.

The Point of View.—Our esteemed contemporary, the *Louisville Medical News*, thinks it would be "better a thousand times" to have no International Congress than to make any concessions to the "bolting specialists of Gotham."

We would have the Committee of Arrangements keep in view the points "that the International Medical Congress has an independent existence with a permanent organization more interested in medical science in the abstract than in local medical politics; that the drawbacks of coming such a distance across the ocean at much expense, especially to men less accustomed and less able to travel than many Americans, can only be overcome by a united and hearty support of the representative men who have thus far been cordially co-operating with Dr. Billings and the members of the Committee of Invitation; and lastly that the 'new code' nonsense had best be allowed to pass into ready oblivion and not be given fictitious importance by further discussion."—*Boston Medical and Surgical Journal.*

"When the feelings of the Association toward the New Code men are remembered, it will be no surprise to learn that the reinforced committee have deposed from any positions of prominence which they may occupy, any gentleman whose record in regard to the Code of Ethics is assailable. Such action at this stage of organization must, however, be contrary to the interests of the Congress."—*The Medical Age.*

A French Prize Awarded to an Englishman.—The French Academy of Medicine has awarded a prize to Dr. Murrell, of the Westminster Hospital, London, for his discovery that nitro-glycerine is a remedy for angina pectoris.

Placebos.—The *Peoria Medical Monthly* criticises as "queer" and dangerous our comments on the ethics of placebo-giving; and it quotes us as saying with reference to the subject: "We feel strongly opposed, however, to erecting such a permissive measure into a canonical fracture," etc. We have never made any such statement as this, and we are profoundly in the dark as to what a canonical fracture is. Our views were frankly, and we thought clearly, stated. Physicians and intelligent laymen know that the former cannot always tell the plain facts to a patient without injuring him. It should be the rule of his life, however, to be straightforward and candid. Therefore, we say that placebos should be, and need be rarely, if ever, prescribed. There is no casuistry about this, nothing "queer" to honest minds, and nothing that need be kept from the public. *Per contra* our valued contemporary feels that there is something in "The Physician Himself" which it would be wise to hide. So far, we agree with him. Against the too obtrusive worldliness which pervades the work in question, we would like to set the maxims which Professor Gairdner has laid down for the guidance of him who would be the ideal physician: "He must have a soul above mere money-grubbing; must, on no account, degrade his profession into a trade; but must be, as far as is possible to human nature, the disinterested friend, the companion, the good genius, I had almost said, of all his patients. He must be a man endowed with a deep sense of moral responsibility, so as to beget confidence

and unfailing trust in him on the part of his fellow-men. Responsibility, therefore, to them in the first instance; but underlying that—and sustaining it as surely as the root and the stem sustain the flower—a deeper and more latent responsibility to Him who is the source of all good, and therefore of all moral principle and moral responsibility whatever." We venture to say that such a man would not find it necessary to keep a polychromatic assortment of sugar pills in his closet.

The Preservation of Chloroform.—Professor Regnauld recently communicated to the Société de Biologie the results of the prolonged researches which he has been engaged in as to the preservation of chloroform. From these it follows: 1, That if absolutely pure chloroform be exposed to solar light, whether direct or diffused, it gives the first indication of decomposition after two days during the high temperatures and intense radiations of July, and only after five days in December; 2, the same chloroform may be preserved pure in contact with the air for more than fifteen months, on the condition of its being scrupulously kept away from solar radiation; 3, the same chloroform, exposed alternately to direct or diffused solar light, may be preserved for more than fifteen months, on the condition of its remaining in contact with the azotized atmosphere completely deprived of oxygen; 4, it has been an error to attribute the changes which take place in chloroform to the presence of a certain amount of free chloral; the oxygen of the air suffices to produce them when the mixture of this gas and the vapors is exposed to insolation; 5, chloroform may be preserved unchanged, even when submitted to the simultaneous influence of air and light, by the addition of a hundredth, a five-hundredth, or a thousandth part of ethylic alcohol; 6, the intervention of ordinary ether ($C_4H_{10}O$) also proves entirely efficacious, since a thousandth part suspended the action of oxygen and light during several months.—*The Practitioner*, May, 1885.

Natural Recovery from a Therapeutical Point of View.—In these days of profound scepticism regarding the efficacy of many of our therapeutical endeavors, it is refreshing to read that all faith in the potency of drugs is not yet dead. Under the above title Dr. J. Mitchell Bruce (*The Practitioner*, April and May, 1885) presents an able and interesting argument to show that therapeutics rests on as sound a foundation as physiology and pathology, because the foundations of the three sciences are essentially the same, and all of them natural. Dr. Bruce concludes his article in the following words: "The morbid anatomist confronts us with a specimen of diseased aortic valves, and asks us what could treatment do for that. We point him to the hypertrophied wall of the left ventricle for the answer. That man is not a pathologist who fails to recognize remedy, not disease, in the thickened parietes. He may show us a phthisical cavity, and we demonstrate to him the evidences that excavation is a process for expelling a foreign and destructive organism, and that repair and localization have been active at every part of the vomica. In the case of those slighter changes in the structure, or it may be only in the functions of organs, which happily do not come under the observation of those who study disease only *post mortem*, we know that many of the phenomena are referable to the reaction of nature against a morbid influence. One and all of these methods are carefully studied and copied by the intelligent therapeutist in the practise of his art, and copied with success, whether by the application of medicinal or of non-medicinal measures. But even more important than this immediate application of the methods of natural recovery is the confidence with which the study of it inspires us, that the science of therapeutics, however backward it still may be, rests on a sound foundation, on the great law of the evolution of all things, and will assuredly one day be reared into a noble structure."

Dr. Robert Koch has been officially gazetted as Professor of Hygiene in the Medical Faculty of the University of Berlin, and has been appointed "Geheimer Medicinalrath."

Death of Professor Panum.—We regret to have to announce the death of Dr. P. A. Panum, the distinguished Professor of Physiology in the University of Copenhagen. Dr. Panum, who was well known for his practical attainments, presided over the International Medical Congress held last year.

The Conference on Cholera at Berlin.—The Conference on Cholera, which met last August, reassembled in Berlin on Monday, May 4th, to hear the result of recent experiments with the cholera bacilli which have been made by Dr. Koch since the last meeting. Professors Virchow, Bergmann, Leyden, Hirsch, Bardeleben; Drs. Skrzeczka, Kersandt, Pistor, Struck, Wolffhügel, Coler, Eulenberg, Fränkel, Gaffky, Neumann, and Schubert, who were present at the last meeting, again attended, and in addition, Professors Pettenkofer, of Munich, and Günther, of Dresden, took part in the present meeting. The Berlin correspondent of the *British Medical Journal* telegraphs that Dr. Koch began by discussing and refuting the views of Finkler and Prior, Klein, and Emmerich. He demonstrated pure cultivations of comma bacilli from France, Italy, and Germany; all these resembled one another. Of one hundred and fifty medical men who attended Dr. Koch's courses of practical instruction, one got "cholerine," and in his dejecta comma bacilli were found. The pure cultivations from Germany, mentioned above, were obtained from this case. Dr. Koch considered that the cholera bacilli belonged exclusively to cholera, that they were easily distinguishable from other bacteria, and hence were serviceable as a diagnostic. He then proceeded to describe the successful experiments on guinea-pigs made with pure cultivations. In the discussion, of which the final reports have not reached us, Professor von Pettenkofer declared himself as yet unconvinced.

The Two Detroit Medical Colleges are to consolidate into one.

An Exhibition of the Bacilli of Syphilis was given by Dr. William H. Porter at the Clinical Society of the Post-graduate Medical School recently. The bacilli were found in a syphilitic lung. This is the first confirmation of Lustgarten's discovery in this country.

Adulterations in Cocaine are already complained of by French surgeons.

At the Thirty-fifth Annual Session of the South Carolina Medical Association, held at Charleston, April 21, 1885, under the presidency of Dr. A. A. Moore, the following officers were elected for the ensuing year: Dr. O. B. Mayer, Jr., of Newberry, President; Dr. Thomas J. McKie, of Edgefield, First Vice-President; Dr. W. P. Porcher, of Charleston, Recording Secretary; Dr. J. L. Dawson, Jr., of Charleston, Corresponding Secretary; Dr. H. W. De Saussure, Jr., of Charleston, Treasurer.

The Mississippi State Medical Association held its Eighteenth Annual Meeting at Greenville, April 15th and 16th. The following officers were elected for the ensuing year: Dr. J. B. Gresham, of West Point, President; Drs. I. B. Pease and S. R. Dunn, Vice-Presidents; Dr M. S. Craft, Corresponding Secretary; Dr. W. E. Todd, of Clinton, Recording Secretary. The Society meets next year at Jackson.

Mamma Aberrans.—Under this title Dr. Cohn, at a meeting of the Berlin Medical Society, recently gave some account of wandering mammary glands, and described a case in which one gland was displaced into the axilla, the child nursing under the arm. Curiously enough, under a similar title, a daily paper gives an account of a mamma who incontinently wandered off and married a second husband, for which act she was indicted.

The Puget Sound Sanitarian is the title of a new journal published at Seattle, W. T., in the interests of hygiene and prohibition. We would call attention to the fact that the editorial statement, "that alcohol has no dietetic value, and that its action on the healthy body is invariably that of a poison, is no longer an open question but a scientific fact," is absolutely false, and it makes a bad beginning for a new journal.

Safe Milk.—Boiled milk.

Death of Professor Frederic Henle.—Professor Frederic Gustave Charles Henle, the well-known German physiologist and anatomist, died in Berlin on Monday, May 18th. Dr. Henle was born in Bavaria in July, 1809, and studied medicine at Heidelberg and Bonn, receiving his medical degree at the latter place. Going thence to Berlin, he entered the College of Anatomy, where, later on, he held an official position. Accused of affiliation with the Socialists, Dr. Henle was thrown into prison. He was soon pardoned, however, and in 1837 he was made a Professor in the Berlin University, where he devoted himself to anatomy and general pathology. Three years later he accepted a chair in the University of Zurich. From 1844 to 1855 he was a Professor in the Heidelberg University, going thence to Göttingen. Dr. Henle was best known for his anatomical writings.

The Inoculations Against Cholera.—The news comes by cable that over 4,700 persons have been inoculated with cholera microbes by Dr. Ferrán in the province of Valencia as a preventive of the disease. The new system is said to be entirely successful, and the epidemic is disappearing. Dr. Ferrán intends to visit England within a few weeks. A commission has been appointed by the British Government to go to Spain and study Dr. Ferrán's methods.

Reviews and Notices.

A Practical Treatise on Nasal Catarrh and Allied Diseases. By Beverly Robinson. Second Edition, pp. 276. New York: William Wood & Co. 1885.

This second edition comes to us in the usual excellent dress of the publishers, Messrs. William Wood & Co., profusely illustrated with wood-cuts representing the appliances and instruments employed in making applications to the nose, or in divesting this useful and ornamental appendage of the defects naturally supplied with so liberal a hand to the rhinologist's skilful manipulations. And as regards instruments, it may truthfully be said that no region of the body affords the surgeon's cutler such a field for the display of his skill, unless, indeed, exception be made in respect to that much favored organ, the uterus. But since the most enterprising gynecologist has thus far failed to discover the uterus in the male, rhinology may be congratulated that man has its analogue in usefulness to him.

In the introductory chapter, it is very properly stated that practitioners stand much in need of a reliable guide in respect to their practice in the diseases of the region under consideration, their confused notions respecting the subject leading to faulty medication, the results of which are often truly deplorable. It gives us pleasure at the onset to say that the requisite familiarity with the rhinologist's armamentarium cannot better be attained than by consulting this reliable manual, since the author has not left the representation of the instruments recommended to the uncertain catalogue of the instrument-maker, but has selected them from numerous reliable sources.

The book is divided into fourteen chapters, the first six referring to the division of the subject, anatomy, physiology and pathology, the examination of the nose, and the instruments required. Chapter VII. is on taking cold; chapters VIII. and IX. on hypertrophy of the turbinated bones and post nasal catarrh. The rest of this interesting work is devoted to aural complications, anomalies of the nose, ulcerous coryza, adenoid growths in the pharynx, and polypi.

The chapters devoted to deflections of the nasal septum, and to hypertrophy of the turbinated bodies, in which the methods in vogue for improving the interior architecture of the nose are presented, are alone worth the price asked for the book. One can but regret, however, that fuller credit is not given the pioneers in this field, since, previous to the ingenious appliances devised by Messrs. Sass and Goodwillie for working in this region, local procedures were much restricted.

The author has availed himself of the assistance of an aurist in arranging the excellent chapter on aural complications. Among other valuable suggestions it is stated that some patients, on coming under the care of the specialist in rhinology, are unwilling to recognize their deafness and appreciate its real gravity, until convinced by examinations, tests of the hearing power, and even close questioning and insisting upon the nature and importance of the aural disorder. Dr. Robinson, being deeply impressed with this indifference of some patients, urges upon rhinologists the necessity of guiding and directing their patients in regard to the hygiene of their ears, and of giving them "the careful, judicious, and learned attention their cases imperatively require, or else direct them to some prominent otologist, who shall do for them what is *most* important for their welfare."

One can but wish that patients belonging to all special branches were more frequently thus aided in comprehending the importance of their symptoms by the kind suggestiveness of those well qualified to advise, and liberal enough to direct them, when thus educated up in regard to their ailments, to the "prominent" specialist.

The profession is very much indebted to the author

for undertaking a treatise covering the ground embraced in the title, and only to the truly envious person could it ever occur that, in taking so much in hand, a greater field for research had been sequestrated than subsequent mastication could properly prepare for the reader's digestion; such thought, if ever entertained, must quickly be dispelled by the intelligent reader on perusing the work, which has the impress throughout of the writer's most lucid and instructive style, a statement which leaves nothing more to be said in its favor. No physician's library can be considered complete without this book, and a large demand for it is predicted.

THE NATURE OF MIND AND HUMAN AUTOMATISM. By MORTON PRINCE, M.D., Physician for Nervous Diseases, Boston Dispensary, etc. 12mo, pp. 173. Philadelphia: J. B. Lippincott & Co. 1885.

THIS work is an elaboration of a thesis written some eight or nine years ago, during the author's days as a medical student, and its scope is well expressed in its title. Our space forbids an adequate criticism of the book. It is replete with matter of interest to the specialist in nervous diseases. Its characteristics are clearness of expression and candor in argument.

Reports of Societies.

ILLINOIS STATE MEDICAL SOCIETY.

Thirty-Fifth Annual Meeting, held at Springfield, Ill., May 19, 20, and 21, 1885.

(By Telegraph to THE MEDICAL RECORD.)

FIRST DAY—TUESDAY, MAY 19TH—MORNING SESSION.

THE meeting was called to order at 10.20 A.M., by the President, DR. J. S. BOOTH, of Sparta.

Prayer was offered by REV. J. S. MUSGROVE.

THE ADDRESS OF WELCOME

was delivered by the present Governor of the State, R. J. OGLESBY. The profession were to be congratulated, he said, in their efforts, as they were purely for the advancement of public health and good. While he knew nothing of medicine as a science himself, he did know that the science could only be promoted by clinical investigation, interchange of opinions, etc. The objects were to separate as far as possible the profession from empiricism and quackery. He knew of no ministers of public good that have it in their power to do so much good as the medical profession. He therefore, on behalf of the citizens of Springfield, heartily commended and welcomed them.

DR. COOK, of Mendota, in a few well-timed remarks on behalf of the Society thanked the Governor for the hearty welcome.

The report of the Committee of Arrangements was, on motion, received and adopted.

The first order of business was the President's address, entitled,

HASH.

He said as life is short we should attend to its duties promptly. Those under our teaching and guidance in the professions should be started out on their professional career properly, but to be able to improve others we must first improve ourselves. We learn in medical societies our duties to our friends, to each other and to ourselves, we learn also to respect the opinions of others, as it is easier to see faults in them than in ourselves. He recommended

STATE LEGISLATION TO REGULATE THE PRACTICE OF MEDICINE, ALSO A STATE BOARD OF EXAMINERS.

Nothing short of common sense would make a good physician, but that alone would not do it. It required the necessary education, etc. He severely condemned the practices adopted with a view to the prevention of conception as well as destroying gestation after once established. All such procedures were not only wrong but pernicious.

The address was received and referred to the Committee on Publication.

The Society then adjourned.

FIRST DAY—TUESDAY, MAY 19TH—AFTERNOON SESSION.

The Society was called to order at 2.30 P.M.

The first paper was the

REPORT BY THE COMMITTEE ON GYNECOLOGY.

by DR. DAVID PRINCE, of Jacksonville. The paper contained a general *résumé* of the recent advancements and inventions in that branch. It had reference principally to the various new instruments which he exhibited.

On motion, the report was received and referred to the Committee on Publication.

The next paper was the

REPORT OF THE COMMITTEE ON OBSTETRICS,

by DR. CHARLES WARRINGTON EARLE, of Chicago. The paper consisted essentially of abstracts, notes, and remarks upon the therapeutics, pathology, and practice of obstetrics. In his remarks on therapeutics, reference was first made to the use of cimicifuga racemosa during parturition, in which he claimed it had a sedative and antispasmodic effect, thereby relaxing the soft parts and making labor shorter and more easily borne. He said recently equal parts of chloroform and sweet oil, applied over the symphisis and on the abdomen, on flannel cloths, had had good results. He thought cocaine could be used on the os uteri with advantage. Bichloride of mercury had, to a certain extent, taken the place of carbolic acid, but experience had shown that it required to be used with caution. The prevalence of opinion favored the idea that puerperal convulsions were the result of kidney derangement. He favored the use of forceps in breech presentations, as also immediate operation in lacerated perineum. In extra-uterine pregnancy he thought the best procedure was to destroy the life of the child with the faradic current, one pole in the rectum and the other over the abdomen.

DR. PRINCE thought the best means for controlling post-partum hemorrhage was to pour ice-water from a distance so that it gradually fell on the abdomen of the woman.

DR. TRUESDALE, of Rock Island, favored postponing the operation for lacerated perineum.

DR. WAXHAM, of Chicago, had never used the curette nor placenta forceps, but used his finger instead for retained placenta, and never lost a case.

The paper was referred to the Committee on Publication.

DR. THOMAS M. MCILVAINE, of Peoria, read

THE REPORT OF THE COMMITTEE ON MATERIA MEDICA AND THERAPEUTICS.

He thought many physicians relied too much on drugs, and it was a fact that the more sanguine they were in their belief in drugs the more they were liable to neglect other important details. There should be more reliance placed upon non-medicinal measures.

DR. S. N. DAVIS, of Chicago, thought it scarcely just to intimate that we had any physician in the profession who thought drugs would cure all diseases. Some, however, had too much faith and some too little.

The paper was referred to the Committee on Publication.

The next paper was

THE REPORT OF THE COMMITTEE ON OPHTHALMOLOGY,

by DR. W. T. MONTGOMERY, of Chicago. He said his results with jequirity were about as follows: Ten per

cent. were cured the first time; twenty-five per cent. were cured the second time; thirty per cent. were improved; fifteen per cent. were not benefited. Allusion was also made to the good results from the use of muriate of cocaine.

Dr. S. J. Jones said so much had been claimed for cocaine that he was afraid it would fail to do all claimed for it, and would therefore fall unjustly into disfavor.

The Society then adjourned.

Second Day — Wednesday, May 20th — Morning Session.

The Society was called to order at 9 A.M.

Professor Henry J. Reynolds, of Chicago, read a paper

ON THE TREATMENT OF ECZEMA.

He said an intelligent knowledge of the principles upon which treatment should be based always suggests the form of treatment that will be applicable to each case regardless of its name or location. The pathological condition being absolutely identical in no two cases, so the treatment must always vary, and a knowledge of specified lines of treatment or combinations of drugs said to be useful, with a neglect of consideration of the principles upon which treatment should be based in each individual case, in this, as in all other diseases, is liable to mislead. Therapeutically speaking, he regarded the disease as always either acute, subacute, or chronic, regardless of its clinical name or location, and arranged the treatment accordingly. In the acute, as in all other acute inflammations, the great principle necessarily involved was rest, which implied not only quietude of the member, or part, but rest from all irritating influences, as scratching, irritation of lice, friction, dirt incident to the calling of the individual, too frequent washing, etc. Soothing and protecting measures, therefore, were indicated in this stage, among which might be mentioned carron-oil, poultices, etc.

In the subacute, as in all other stages or forms, scratching must be strictly prohibited, as it was the most fruitful of all sources of aggravation. He used in this and the chronic conditions (either of which may at any time develop acute symptoms, and require the treatment changed accordingly) pure, impalpably fine boracic acid as a dusting powder, having first gotten rid of crusts and scales by soaking with oil and washing with soap and warm water. In the chronic, however, he used greater stimulating measures, in the way of green soap, frequently rubbed in during washing. To relieve intense itching he had found nothing so effectual as a first-class letting alone. He thought bandaging and strapping advisable whenever practicable, and preferred the cotton roller to the rubber where there was much exudat on or maceration of the skin. He reported two cases, of twelve and twenty years' standing respectively, of eczema rubrum of the leg associated with varicose veins and ulceration, where many remedies had been tried without success, that he cured by the application of boracic acid and bandaging.

He said, as certain constitutional conditions predispose to the disease, and therefore necessarily aggravated or prolonged it when once established, these conditions must be sought after and corrected. He had but little faith in the popular skin remedy, arsenic, in this or any other disease. All he knew positively of the remedy was that harm could be done with it. Chrysarobin internally, as recommended by Stoquart, he had tried without any benefit.

A report from the State Board of Health was received, and referred to the Committee on Publication.

Several bills now before the Legislature in the interest of the people of the State, as well as the medical profession, were discussed by Drs. Rausch, of Springfield, N. S. Davis, and A. B. Strong, of Chicago.

The report of the Committee on Necrology was read by Dr. M. F. Bassett, of Quincy, and referred for publication.

Dr. J. P. Mathews presented a case of a young man in whom typhoid fever had been followed by an

ULCER JUST BELOW THE VOCAL CORDS,

with great obstruction.

TRACHEOTOMY WAS PERFORMED LAST JANUARY, AND THE TUBE WORN EVER SINCE,

as he could not breathe freely without it till recently. There was no evidence of syphilitic or tubercular trouble.

The paper was discussed, and similar cases reported by Drs. Ingalls and Waxham, of Chicago, and Dr. Pruitt.

Prof. Hoadley, of Chicago, read a paper on

TOO OFTEN FEEDING

as a cause of disease, and a protest against one cow's milk. Several cases were reported by the author, showing the very beneficial results when the frequent feeding was discontinued, and the child fed at regular intervals. He said there were a great many reasons why the milk should be changed if the child did not do well, especially if the cows are kept in town.

Drs. Byford, Jr., and Waxham made remarks in the discussion.

Dr. Truesdale, of Rock Island, then made the report on "Traumatic Tetanus," which was read and referred.

THE REPORT ON NOMINATIONS

was received and adopted.

THE REPORT ON INSANITY

was read by Dr. R. J. Patterson, of Batavia, and referred to the Committee on Publication.

Dr. M. F. Bassett, of Quincy, read a paper on

ALCOHOL AS A THERAPEUTIC AGENT,

in which he claimed that, while admitting the drug to be useful in many instances, the bad moral effect so frequently caused by it more than offset its good.

It was referred for publication.

The report on "Physiology" was read by Dr. A. Wetmore, of Waterloo, and was referred for publication.

Professor E. Fletcher Ingalls, of Chicago, read a paper

ON RECURRENT LARYNGITIS,

and its relations to hypertrophic catarrh, in which he concluded as follows:

"1, The affection was usually dependent upon nasal obstruction; 2, the obstruction, in the majority of cases, was due to deflection and thickening of the septum or hypertrophic catarrh; 3, to effect a permanent cure, local remedies were unreliable, and the obstructing tissues must be removed; 4, operative procedures for removal of these obstructions may be made painless by the use of hydrochlorate of cocaine; 5, this method of treatment, properly carried out, may be relied on to cure the catarrh, and the laryngitis of which it was the cause; 6, great improvement in the general health of the patient often immediately follows the removal of the nasal obstructions; 7, in acute catarrh immediate relief may be obtained by insufflation of small quantities of cocaine."

The paper was referred for publication.

Dr. D. R. Brower, of Chicago, read a paper on the

TREATMENT OF EPILEPSY.

Dr. Byrd thought that when trephining was not successful, a larger portion of bone should be removed.

The paper was referred for publication.

Dr. H. R. Guthrie, of Sparta, read a paper on

MEDICAL EDUCATION,

which was referred to the Committee on Publication.

(To be Continued.)

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Eighty-seventh Annual Session, held in Baltimore, Md., May 12, 13, 14, 15, and 16, 1885.

(Continued from page 551.)

THIRD DAY—THURSDAY, MAY 14TH.

DRS. GEORGE J. PRESTON, W. J. Jones, Samuel T. Earle, William T. Councilman, E. E. Mackenzie, and B. W. Goldsborough were elected members. Drs. E. J. Williams and M. B. Billingslee qualified as additional delegates from the Medical and Surgical Society of Baltimore.

REPORT OF THE SECTION ON PRACTICE OF MEDICINE.

DR. JOHN S. LYNCH presented a report on

ANTIPYRIN

Its discovery, he said, was scarcely less important than that of quinine. By it febrile temperature, under whatever circumstances it occurs, can be absolutely controlled. He had used over fifteen ounces of it since last November, and in a great variety of affections—phthisis, rheumatism, typhoid fever, pneumonia, malarial fever, etc. With but two exceptions he found it certain, safe, and reliable. In rheumatism, he found it quite as curative as salicylic acid. In malarial fever it hastens defervescence, converting a remittent into an intermittent fever, and rendering quinine much more efficient; it has no curative power, however, in malarial affections. No giddiness, headache, or tinnitus aurium follow its use; in two cases it produced vomiting, which readily ceased on its discontinuance. Ordinarily fifteen to twenty-two grains every two to three hours are sufficient. Its effects ensue rapidly—in one or two hours; it thus possesses great advantages over quinine. But its action is much more transient than the latter, and hence it must be given longer and more frequently. The first dose usually causes sweating, which is sometimes copious. Given during the paroxysm of intermittent fever, it prolongs the intermission. It is soluble in its weight of water, and is not disagreeable to take (as quinine and salicylate of sodium are). If continued in some cases, it causes an inconsequential eruption.

DR. R. H. THOMAS referred to the

ANTIPYRETIC POWER OF KAIRIN

in phthisis, acute rheumatism, etc., in five to ten grains every hour. It will reduce a temperature of 103°–104° F. in two or three hours to 99°; when it reaches this point he suspends. An experience of eighteen months convinced him of the necessity of using caution, as alarming depression may result from a negligent use of the drug. When the temperature has been once reduced quinine will often keep up the effect.

DR. R. WINSLOW had employed kairin in a boy with typhoid fever in five-grain doses. It produced alarming but not fatal collapse.

The Report from the Section on Materia Medica and Chemistry was, on motion, referred to the Publication Committee, on account of the unavoidable absence of the Chairman, Dr. Eugene F. Cordell.

REPORT OF THE SECTION ON ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

DR. WILMER BRINTON presented a report on pathology, giving a review of the researches regarding the cholera bacillus, the micrococcus of pneumonia discovered by Friedlander in 1883, Eberth's bacillus of typhoid fever, and Lustgarten's syphilis bacillus.

RECTAL MEDICATION.

This was the title of a paper by DR. D. W. CATHELL, author of "The Physician Himself." The advantages of rectal suppositories not only in pelvic but other affections were advocated, especially in administering morphia and belladonna.

REPORT OF THE SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

DR. FRANK DONALDSON read a paper from this section on "Personal Observations on the Value of Hydrochlorate of Cocaine in Nose and Throat Surgery." He had used it daily since its discovery by Koller last September, and found it of great value as an astringent, a hemostatic, and a local anæsthetic in removing nasal polypi and other operations about the nose and throat. Its value was conspicuous in the dysphagia of tuberculous laryngitis. It was also very valuable in the thickening of the nasal mucous membrane, rendering operations by knife, snare, and galvano-cautery painless.

DR. JOHN N. MACKENZIE did not think much was to be expected from it in acute and chronic congestion of the nasal mucous membrane, as its effects were very transient.

DR. R. H. THOMAS referred to its value in facilitating examination of the nasal cavities by shrinking the membrane.

DR. HERBERT HARLAN presented a report on Ophthalmology from the same Section.

FOURTH DAY—FRIDAY, MAY 15TH.

Drs. G. T. Atkinson, of Crisfield; H. H. Biedler, of Baltimore; and B. R. Benson, of Cockeysville, were elected to membership.

REPORT OF THE SECTION ON SANITARY SCIENCE.

DR. W. CHEW VAN BIBBER read a paper on

TRAVELLING AS A TONIC.

DR. GEORGE H. ROHÉ, of the same Section, read a paper on

THE NON-NECESSITY OF ANY RADICAL CHANGE IN THE PRESENT SYSTEM OF DISPOSAL OF THE DEAD.

In this paper Dr. Rohé undertook to prove that burial was a harmless method; the opposition to it, he said, emanated from some "supposed" sanitary authorities. There is very little trustworthy evidence that cemeteries are injurious to the health of those living near them. The good health of workmen in them and in knackeries contradicts the opinion that gaseous emanations from decaying animal matter are dangerous to health. Micro-organisms are not moved by air-currents when attached to a moist surface. Wells near cemeteries, as a rule, furnish water as pure as that from places inhabited by living human beings where the soil is more or less polluted. There is no safe basis for the conclusion that infectious diseases and epidemics may be communicated through air, water, or soil of cemeteries. The evidence of the dangers of burial during epidemics lacks accuracy. The greatest violence of disease in several yellow-fever epidemics and in the small-pox epidemic in this city in 1883, was not in the vicinity of cemeteries. He maintained that the expense of cremation would be as great as a first-class funeral. It is claimed that during epidemics bodies can be disposed of more rapidly and effectually by cremation than by burial. There are twenty-three deaths daily in this city (Baltimore), which would require four crematories.

Suppose the number increased to one hundred, would it be possible to reduce that number to ashes with ordinary arrangements? A fatal objection to burning bodies is that in cases of criminal poisoning cremation would destroy all evidences of the crime. When bodies are buried in suitable soil the decay goes on rapidly and without offensive emanations.

The following were Dr. Rohé's conclusions: 1. Cremation is not necessary as a sanitary measure under the conditions prevalent in this country. 2. It has no ad-

vantage on the score of economy over interment. 3. It fails to meet the requirements of epidemics or wars as well as burial. 4. It is objectionable from a legal point of view, as criminal poisoning would often pass undetected if incineration were general. 5. It fails to comply with the emotional demands of our nature by substituting a harsh and unseemly procedure for the more poetic and sentimental slow dissolution going on in the grave.

Dr. John Morris said that after the refutation of Dr. Rohé's views at the meeting of the American Public Health Association in St. Louis, he did not expect to hear from him. Crematories are valuable in epidemics; fire is the great purifier and will be to the end.

Dr. Van Bibber suggested that a body could be held for examination when there was suspicion of crime.

Dr. J. C. Thomas said embalming by the use of poisons was open to the same objection.

Dr. James Carey Thomas, from the same Section, presented a paper on

THE IMPORTANCE OF THE SPECIAL TEACHING OF SANITARY SCIENCE AND PREVENTIVE MEDICINE.

Physicians, he said, should be able to advise the municipal and district authorities on matters relating to public health as well as to so study the constitution, habits, and surroundings of the families and individuals committed to their care as to be able to hinder them from falling a prey to preventable sickness. The disastrous epidemic of typhoid fever at Plymouth, Pa., is a recent example of the fatal effects of the disregard of the obvious sanitary precautions in the pollution of drinking-water. It is proposed to introduce the study of elementary physiology and hygiene into the public schools of Maryland, and it is important that physicians educated in our medical colleges should keep in advance of public intelligence in this direction. The Illinois State Board of Health place hygiene among their minimum requirements, and state that in 1883 it was taught in sixty-four medical schools in the United States.

There was no report from the Section on Microscopy, Micro-Chemistry, and Spectral Analysis.

REPORT OF THE SECTION ON PSYCHOLOGY AND MEDICAL JURISPRUDENCE.

The report was presented by Dr. J. S. Conrad, Chairman, who took for his subject "Insanity." Dr. Conrad quoted statistics to show the great growth of insanity in this country. During 1870–1880, according to the census, the increase of population was 30 per cent., while the number of insane increased 155 per cent. It would appear that there are 400,000 persons in this country either insane, or in institutions of some kind for their safe-keeping. During 1875–1880, the number of institutions for the reception of the insane increased from 68 to 139, with 40,942 in hospitals, costing nearly double as much as in 1875. The State Insane Hospital of Maryland in 1875 contained 170 patients, in 1884 it had 494; Mount Hope had in the former year 279, and in the latter 477. He knew of no harder worked men and women; hence neglect of patients. The remedy is to separate the acute and chronic cases, with cheaper accommodation for the chronic, who chiefly need only custodial supervision. At present the superintendents are unable to give medical attendance in consequence of their executive duties; consequently treatment is left to assistants—young men, as a rule, unqualified for the duties, and frequently appointed for political preferment, as are nurses and attendants. There is almost a complete absence of any systematic study of brain diseases. How many in this learned body ever heard a lecture on insanity in any medical school? How many ever read a systematic work on insanity, and how many ever saw or studied half a dozen cases of the disease in its different forms? Suppose these questions could be asked of you as to other branches of medicine or surgery with similar results, and who would consult with such a person? The graduate student may be in theory informed as to the significance of a mitral or aortic murmur, but if his ear is not educated by experience is it not a serious question if he really can recognize them?

The sounds which come from the brain are far more complicated than those from heart or lungs. How, then, can we expect one without instruction and experience to form an intelligent idea as to what the mental condition of an insane patient may be. What is the difference between an hallucination and an illusion of sense—an hallucination and a delusion? Why is it that an hallucination may be a delusion, and the latter not the former? What is the difference in point of knowledge between a doctor who has not studied the subject of insanity and a layman, when they give opinions on the subject? Not one whit, except that one has an M.D. to his name, and the other has not; that is all. Yet there are many medical men who will dare assert an opinion on the witness stand in a question of insanity which he has never studied. A noted gynecologist in the Guiteau case was positive of the prisoner's insanity. Such self-assertion often brings the profession into contempt. We have two medical schools in this State—one of them one of the oldest in the Union. Each has a faculty of acknowledged ability. One has only in the last two years taught the subject of insanity in its curriculum; the other never has. But in this our State is not far behind other States.

Dr. Conrad also replied to the statements made by Mrs. Packard, the lady who had addressed the faculty at the second day's session (as already mentioned). Mrs. P. had asserted that there was a large number of persons confined in insane asylums who were perfectly sane. The assertion was supported, he said, only by herself. No such case came under Kirkbride's notice in over fifty years' experience with the insane, nor under that of the superintendents of asylums convened in Washington in 1878. Her charge that persons are buried from knowledge of friends for years is unfounded; does she forget the habeas corpus act, or that asylums are under the government of State Boards of Directors? Were the alleged falsely-confined persons examined by an expert there would be found good cause for their detention—as in the Lyman case and others.

If the law required security for safe-keeping of those removed by process of law there would soon appear another side to these cases. A few years ago a Captain Ames was committed to Mount Hope Retreat. He was discharged by habeas corpus, a jury deciding he was sane; but shortly after he fired three shots at two persons in the dining-room of his boarding-house, one of whom he had never spoken to. If those securing his release had been obliged to give security they might have had more regard for the opinion of others who had some knowledge of insanity. In another case, where a husband removed his wife, she soon after shot him fatally while sleeping by her side. A third case which has brought calamity on two prominent families of this State by the death of a gentleman at the hands of an insane man will also be recalled. There can be no objection to the placing of mail-boxes in all the wards, provided letters are overlooked by the board of managers or a lunacy commission as in Massachusetts and other States. If there were no supervision, patients would constantly expose themselves and frequently use such obscene language as would give pain to their friends and to the patients themselves in case of recovery. Outcries against insane asylums came often from that class of insane persons who are sane enough to deceive those who know nothing about the subject, but crooked philanthropy and humanitarianism is all nonsense when we hear of the murder of some of our best citizens and innocent children by the insane in almost every issue of the daily press.

Dr. Gundry had heard from Mrs. Packard before. He had not the slightest objections to postal conveniences for patients, but if a superintendent will read letters improperly, will he not tamper with boxes? For twenty-

five years his patients have had their letters unopened. On the whole he thought it best not to break the seals of the letters, yet there is now a patient whose letters he would not for the world let go out as written.

Dr. Randolph Winslow read a volunteer paper on "Six Cases of Gunshot Wounds of the Abdomen."

Dr. John N. Mackenzie read a paper entitled

OBSERVATIONS ON THE ORIGIN AND CURE OF THE DISEASE CALLED "HAY ASTHMA" (CORYZA VASOMOTORIA PERIODICA),

of which the following is an abstract: Ignorance of intranasal pathology on the part of those investigating the complaint, false theories, and especially the pollen theory, have, by drawing attention to less essential conditions, been barriers to therapeutic progress and have contributed to the sufferings of the patient. After criticising the various theories on the subject, Dr. Mackenzie proceeded to show that the disease called hay fever is no new affection, but has descended through the centuries under the guise of the convulsive asthma and nervous coryza of the older writers and nosologists, and that the so-called idiosyncratic influence in its production may be traced in all probability to the time of Galen. Dr. Mackenzie does not regard the disease as an affection of any particular century, or confined to any condition of mankind. According to his conception the affection commonly known as "hay fever" is simply a grouping together of certain prominent and frequent symptoms of a particular form of nasal inflammation to which he has given the name *rhinitis sympathetica*, characterized by a peculiar excitability of the nasal cavernous tissue possibly linked to an exalted state of the nerve-centres (see abstract in *Maryland Medical Journal*, April 11, 1885; see also on pathology of the affection, *Trans. American Laryngol. Assoc.*, 1884, p. 113, and articles in New York Medical Record, for July 19 and October 18, 1884).

To the intelligent treatment of such cases certain principles should be borne in mind which underlie the etiology and mechanism of the paroxysms. It should be borne in mind that the excitability of the turbinated tissue is a secondary phenomenon dependent, as a rule, upon a direct impression made upon the sensitive nerves of the mucous membrane and upon the terminal filaments of the olfactory; or an indirect influence conveyed or reflected through the vaso-motor centres from a distant organ; or finally, from some excitation starting in the centres themselves. This stimulation of the nerve-centres, from whatever cause originating, is reflected outward probably through the sympathetic filaments which reach the turbinated structures with the spheno-palatine nerves. Now, as these nerves are distributed over the posterior and inferior portions of the nasal fossæ (sensitive reflex area), the turgescence of the erectile tissue is most noticeable over this particular area, and it will be found that this surface represents the most sensitive spot to the reflex-producing impression.

Destruction of the terminal filaments of the sensitive nerves accomplishes thus one result—it closes one door against *ab extra* irritation of the nerve-centres. In order to exclude completely the influence of the latter, it is necessary in addition to remove all sources of local irritation, from whatever cause originating. In this way the production of paroxysms from external agents acting directly on the nasal mucous membrane is prevented. The above measures alone are obviously insufficient to protect from paroxysms due to agencies operating within the organism, or from reflected irritation from other parts of the body. The indication here is to remove the cause and diminish or abolish the reflex excitability of the erectile tissue—mark it, not to produce artificial contraction of its muscular elements, whose inevitable result will be permanent weakening and dilatation of the intercellular walls, but so to alter the nutrition of the nerve-centres that they may not respond so easily to impressions which awaken the reflex. Failing in the above methods, the destruction of the cavernous tissue should be undertaken. In the majority of cases it is neither necessary nor advisable to destroy a large portion of the cavernous bodies; the amount to be sacrificed depends upon the exigencies of the particular case. Dr. Mackenzie does not usually wait for the interregnum of immunity, but operates between the paroxysms, and by this means has succeeded in preventing their return, even when the individual has been exposed to the exciting causes of the paroxysm. He makes a stellate incision with the cautery knife in the tissue to be removed, the advantage of which resides in the resulting cicatrix and the greater potency of the nostril secured therefrom.

The prognosis depends not only upon the special predisposing and exciting causes of the disease and the facility of their removal, but also upon the amount of structural injury done to the respiratory organs, to the central nervous system, and to other parts of the body subjected to the reflex disturbances to which the frequency of the paroxysms has led. In general, it is good, relief can always be secured, and in a fair proportion of cases a cure may be effected.

TUMOR OF PYRIFORM SINUS.

Dr. John N. Mackenzie exhibited a tumor about the size and shape of the testicle, removed from the right anterior inferior segment of pyriform sinus of a clergyman, who for eight months had had symptoms of obstruction of the throat and nightly suffocative attacks. Tumor filled sinus, riding over epiglottis, depressing it, and hiding greater part of larynx. Deep situation of its broad pedicle made operation with mirrors difficult. Retching took place, whereupon the growth was seized with forceps; an écraseur was passed over forceps to base of tumor and growth was completely removed. No bad after-symptoms. Microscopic examination by Dr. Councilman showed areolar connective tissue in which small areas of lymphoid cells similar to the "lymphoid" corpuscles were embedded, the masses being most abundant under the epidermis covering the growth. There was no trace of glandular structure.

Fifth Day—Saturday, May 16th.

Dr. C. O'Donovan, Jr., read

A REPORT OF FIVE CASES OF OVARIOTOMY

from the records of the Hospital for the Women of Maryland, of Baltimore City. These cases had occurred in the service of Dr. William T. Howard, one of the attending surgeons. Four recovered and one died.

Dr. Howard, who was present, said that the death of the fatal case was almost a foregone conclusion, no hope being entertained of her recovery. The autopsy revealed malignant disease. With regard to the significance of albuminuria, he did not consider Bright's disease in moderate degree as a contra-indication to the operation. If we rejected all cases of albuminuria we would reject many that recover. Wherever there is congestion there will be albuminuria. All forms of casts known may be found during pregnancy, yet recovery may be complete, and instances of patients living many years with evidences of structural disease of the kidneys are not uncommon.

Dr. Lynch urged the importance of examining the urine before all surgical operations. If the kidneys are found to be structurally affected, no serious surgical operation should be undertaken.

Dr. Christopher Johnston read a paper sent him by a former member of the Faculty, Dr. David Stewart, now of Port Penn, Del., upon "Carbon as an Antiseptic Dressing for Wounds."

Dr. Tiffany thought the use of this substance objectionable, on the ground that it would be likely to occasion discolorations of the surface, not unlike those produced in tattooing with india-ink.

Dr. F. Donaldson, Jr., presented a paper, "Abstract

of a Paper on Tonsillar and Labial Chancre in a Woman, constituting a Syphilitic Reinfection."

Dr. J. H. Branham read a paper on "Stricture of the Urethra," with specimens.

Dr. J. E. Michael read a paper for Dr. W. S. Maxwell, of Still Pond, Kent Co., Md., on "A Case of Pericolitis due to Perforation of Bowel." An abscess behind the colon on left side, due probably to some foreign body which had escaped from the intestine, burst into the peritoneum with fatal peritonitis.

This concluded the reading of papers, and the remainder of the session was devoted to receiving reports and transaction of business.

The Committee of Trustees of Building Fund, having accomplished nothing, was discharged.

Dr. T. Barton Brune reported that the Directory for Nurses was not in a flourishing condition. There were only sixty nurses on the register. There was a cash balance for the year of $33.33.

Dr. Christopher Johnston thought the advent of the Sisters of Bon Secours, who were skilled nurses, accounted for the paucity of results.

Dr. Brune thought not, as there were only fourteen of the Sisters, and there ought to be employment in a community like this for several hundred nurses. He had endeavored to have the Sisters register, but ineffectually.

The Committees on Legislation relating to the insane, to sale of poisons, to practice of anatomy, to instruction of feeble-minded children, were continued.

Dr. George H. Rohé, of the Committee on the Relations of the Medical Profession to Certain Sanitary Needs of the Community, made a report, in which the deficiencies of legislation in regard to purity of water, food, and medicines, the professional standard, a sanitary survey of the State, regulation of the social evil, etc., were discussed.

In accordance with the recommendations of the report a Committee on Public Hygiene, to be the medium of the Faculty in its intercourse with the public or its legal representatives, but without power to act finally until its conclusions have been ratified by the Faculty, was appointed, consisting of Drs. Geo. H. Rohé, E. G. Waters, and J. Carey Thomas.

Dr. J. E. Michael's amendment to the constitution, changing the word "gentleman" to "person," the object being to make female physicians eligible to membership, was adopted without dissent.

On motion of Dr. R. Winslow a committee of five was appointed to memorialize the Legislature with regard to the passage of a law regulating the practice of medicine in Maryland, the Committee's report to be first submitted to the Faculty before presentation.

The Committee on Precautions against the Threatened Cholera Epidemic made an incomplete report; among other things the measures recommended in the address and report of the American Public Health Association had been adopted by the Committee.

ELECTION OF OFFICERS.

The following officers were elected for the ensuing year:

President—John R. Quinan.

Vice-Presidents—E. C. Baldwin and J. Edwin Michael.

Recording Secretary—G. Lane Taneyhill.

Assistant Secretary—Robert T. Wilson.

Corresponding Secretary—T. Barton Brune.

Treasurer—W. F. A. Kemp.

Executive Committee—T. S. Latimer, P. C. Williams, L. M. Tiffany, H. P. C. Wilson, and Christopher Johnston.

Board of Examiners of Western Shore—Chew, Opie, W. M. Kemp, Friedenwald, Cathell, Ashby, and C. H. Jones.

Board of Examiners of Eastern Shore—Atkinson, Bayly, Chamberlaine, Bordley, and Maxwell.

Delegates to Medical Societies—Virginia: Drs. Wm. Lee, Chisolm, and H. P. C. Wilson. West Virginia: Drs. McComas and Brinton. Alabama: Lynch and Browne. Pennsylvania: Barron and Taneyhill. New York: Morris and Perkins.

THE FOURTH GERMAN CONGRESS OF INTERNAL MEDICINE.

Held in Wiesbaden, April 8, 9, 10, *and* 11, 1885.

Professor Gerhardt, President, in the Chair.

(Special Report for The Medical Record.)

The success which had attended previous meetings of the Congress for Internal Medicine was more than equalled on this occasion. More than two hundred and fifty physicians were present, representing Germany, Austria, Switzerland, Holland, and America. Prominent among these were Binz, of Bonn; Donders, of Utrecht; Filehne, of Erlangen; Fraentzel, of Berlin; Gerhardt, of Würzburg; Hack, of Freiburg; Immermann, of Basel; Koerte, of Berlin; Leube, of Erlangen; Leyden, of Berlin; Liebermeister, of Tübingen; Meynert and Nothnagel, of Vienna; Preyer, of Jena; Senator, of Berlin; Vierordt, of Tübingen; Weigert, late of Leipzig; and Ziegler, of Tübingen.

First Session—April 8th, 9 A.M.

Professor Gerhardt, of Würzburg, in the Chair.

In opening the meeting, the Chairman paid a glowing

TRIBUTE TO THE MEMORY OF THE LATE PROFESSOR FRERICHS,

who had presided at the first three meetings of the Congress.

The list of Vice-presidents and Secretaries was then announced, and the first paper of the meeting read, on

THE TREATMENT OF CORPULENCE,

by Professor Ebstein, of Göttingen. The essential elements of the Ebstein method consist in the withholding of all carbo-hydrates, and, as far as possible, fluids, from the diet of the patient. Fats are allowed. Not the least advantage of the method is the fact that the patients suffer little or no inconvenience, and the treatment may be kept up indefinitely. Excellent results are reported; but marked success is not to be expected under several months.

Professor Henneberg, of Göttingen, followed with a paper on the same subject. In the discussion Bauer (Munich), Zuntz (Berlin), Meinert (Dresden), Unna (Hamburg), Baelz (Japan), Leube (Erlangen), and Jürgensen (Tübingen), took part.

Second Session, April 8th, 3 P.M.

Professor Mosler, of Greifswald, in the Chair.

Professor Hack, of Freiburg, read a paper on

THE SURGICAL TREATMENT OF ASTHMA.

The importance of treating any lesions of the nasal mucous membrane, as polypi, etc., was emphasized. Discussion postponed.

Dr. Lustgarten, of Vienna, gave a demonstration of the

SYPHILIS BACILLI

recently discovered by him. The bacilli, which resemble those of tuberculosis and lepra, occur constantly in syphilides. They are always enclosed in cells, probably wandering cells.

Dr. Pfeiffer, of Wiesbaden, gave a demonstration of the

CHOLERA BACILLUS.

Professor Bostroem, of Giesen, read a paper on

ACTINOMYCOSIS.

Dr. Unna, of Hamburg, presented a patient who had been successfully treated for

LEPRA TUBEROSA

with pyrogallol, chrysarobin, and ichthyl, successively, the remedies being exhibited both internally and externally. Ichthyl was regarded as possessing the most favorable action. In the discussion which followed, Baelz (Japan) and Schultz (Kreuznach) took part.

Professor Immermann, of Basel, read a paper on

LATENT ARTICULAR RHEUMATISM.

The disease is characterized by obstinate neuralgia of the second branch of the trigeminus, accompanied by high fever, occurring during epidemics of articular rheumatism, and resisting all ordinary treatment, but yielding promptly to sodii salicylicum. In the discussion Edlefsen, of Kiel, corroborated these observations.

Third Session, April 9th, 9 A.M.

Professor Gerhardt in the Chair.

Professors Filehne, of Erlangen, and Liebermeister, of Tübingen, read papers on

ANTIPYRESIS,

the former discussing the chemistry of the antipyretics, the latter treating the subject from a clinical standpoint. Discussed by Jaksch (Vienna), Zuntz (Berlin), Strümpell (Leipzig), Bauer (Munich), Rossbach (Jena), Hintzing (Munich), Heubner (Leipzig), Thomas (Freiburg), and Jürgensen (Tübingen). There was but little difference of opinion among the speakers, the general verdict being exceedingly favorable on the action of antipyrin. This remedy and the cold bath were regarded as the most reliable means of combating the most dangerous symptom in febrile diseases. The drug is to be given in doses of one and two grammes.

Zuntz, of Berlin, then exhibited specimens and charts in illustration of the

NEWLY DISCOVERED CENTRE IN THE NUCLEUS CAUDATUS,

a lesion of which is followed by hyperpyresis.

Fourth Session, April 9th, 3 P.M.

Professor Körte, of Berlin, in the Chair.

Professor Meynert, of Vienna, read a paper on the

MECHANISM OF INSANE IDEAS,

a paper which it would be impossible to adequately notice in brief here.

Dr. Edinger, of Frankfort, gave a demonstration of the

COURSE OF THE SENSORY FIBRES OF THE BRAIN.

Dr. Liebig, of Reichenhall, read a paper in which the favorable action of high

ATMOSPHERIC PRESSURE IN ASTHMA

was explained mechanically as due to the forcible dilatation of the small air-passages and vesicles.

Professor Rossbach, of Jena, followed with a paper, giving the results of experiments on dogs, on

MOVEMENTS OF THE STOMACH

in different conditions of dilatation with solids and fluids.

Fifth Session, April 10th, 9 A.M.

Professor Gerhardt in the Chair.

Dr. Curschmann, of Hamburg, read a paper on

BRONCHIAL ASTHMA.

The speaker emphasized the differentiation of asthma into two groups: Primary, in which the lesion is to be sought in the nerve-centres; secondary, in which the lesion is peripheral. The latter is again divided into two varieties: Those cases in which there is and those in which there is not an observable lesion of the respiratory organs. The treatment is divided into two classes: That directed toward relieving the patient during an attack (narcotics, belladonna, lobelia, etc.), and that aimed at removing the causal conditions of the disease. For the latter, arsenic, quinine, and the persistent use of iodide of potassium were recommended. The speaker was followed on the same subject by Professor Riegel, of Giesen. Discussion by Professors Donders (Utrecht), A. and B. Fraenkel (Berlin), and Drs. Schmidt (Frankfort) and Ungar (Bonn).

Sixth Session, April 10th, 3 P.M.

Professor Fraentzel, of Berlin, in the Chair.

Dr. Pfeiffer, of Wiesbaden, demonstrated a case of

RHEUMATISMUS NODOSUS,

in a boy nine years of age. Only twenty-seven cases of this rare disease have been reported.

Professor Fürbringer, of Jena, read a paper on

ALBUMINURIA IN SYPHILIS.

The speaker called attention to the frequent occurrence of albuminuria in secondary syphilis. Of two hundred cases eight per cent. of those which were treated with mercury became albuminuric; while in twelve per cent. of the cases not treated with mercury, albuminuria occurred in the roseola stage. In the latter, the albuminuria disappeared on the commencement of treatment with mercury. These cases were regarded as aborted forms of acute infectious nephritis—the former being probably cases of toxic glomerulitis.

Dr. Schuster, of Aix-la-Chapelle, reported similar cases.

Professor Fleischner, of Erlangen, read a paper on

URÆMIA,

in which he occupied himself with advancing proofs against the theories of Traube, Frerichs, Voit, and Oertel.

Professor Edlefsen, of Kiel, presented statistics of eight hundred cases of

ACUTE ARTICULAR RHEUMATISM,

occurring during several years, in Kiel. But little new was added to our knowledge of the subject, except that the disease showed a tendency to show itself in particular sections of the city, many cases appearing even in the same house.

Professor Jürgensen, of Tübingen, and Dr. Friedlaender, of Leipzig, reported similar experiences, the disease occurring often as an epidemic in barracks and garrisons.

At the seventh and last session, April 11th, 9 A.M., after a brief report by Professor Binz, of Bonn, on new remedies, and the report of progress from the Committee on Infectious Diseases, the result of the

ELECTION OF OFFICERS

for the ensuing year was announced, and Wiesbaden was appointed as the place of meeting for the next Congress, in 1886.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING OF THE SUMMER SESSION—THE LECTURE SYSTEM—CHANGES IN THE CURRICULUM—THE NEW LIST OF FELLOWS AT THE COLLEGE OF PHYSICIANS.

LONDON, May 2, 1885.

THE summer session nominally commenced yesterday. Next week it will begin in real earnest, and by the time this reaches you eleven sets of lecturers will be hard at work doing what could be accomplished with equal efficiency by half their number. I refer here merely to the lecture system. There is no fear of any real surfeit of practical teaching in London any more than elsewhere. With so many as eleven schools of medicine in the metropolis it is scarcely possible to secure first-class teachers for all, and the smaller ones necessarily suffer. Where there are but a few students, it is not possible to pay enough to obtain the best teachers, or to retain them when they have been secured. Many men join the teaching staff of a small school for a year or two, and leave when "they can get something better." In some respects the larger schools possess obvious advantages. With ampler funds at their command, they can offer sufficient salaries to induce the professors of the more scientific parts of the curriculum to devote the whole—or, at any rate, a large portion—of their time to teaching or research. The smaller hospitals cannot do this, and the lecturers on anatomy, physiology, and cognate subjects can only afford to give up a fraction of their time to scientific work. Their chief aim is to obtain practice, and they only spend some of their time in instructing for the sake of a little augmentation of their incomes while waiting for practice.

Signs are not wanting that the lecture system is doomed—at any rate, in its present form. The "Conjoint Board" have issued regulations, according to which attendance on lectures on the following subjects, viz., chemistry, botany, and materia medica, is no longer compulsory. All that they demand is that the student must present certificates showing that he has "received instruction" in each of these subjects. In accordance with this rule, students now entering will be allowed to present themselves before the Conjoint Board in July, for examination in chemistry and chemical physics, materia medica, pharmacy, and medical botany. Now there are no *lectures* on chemistry in the summer session, but only a practical course. The systematic lectures on that subject are given in the winter session.

The "Conjoint Board for England" has been received with a good deal of opposition, especially from the medical journals here. It is, however, a reality now. Its practical effect will be to render the entrance to the profession more difficult. Ten or fifteen years ago it was not at all uncommon for a certain proportion of students to take advantage of the rule of the College of Surgeons, whereby eighteen months out of the four years were permitted to be spent either at a provincial hospital or in apprenticeship to a general practitioner. In this case only the minimum of time—three winter and two summer sessions—was spent in London. Now, however, with increasing complexity and stringency of the examinations, it is by no means uncommon for an additional year to be spent at a London hospital over and above the full four years. The commencement of medical study by a period of pupilage is, too, decidedly less frequent.

Fresh heartburnings are rife just now among London physicians in consequence of the new list of Fellows published by their college. Some affect to consider it a liberal list, but any one can see with half an eye that it is quite the reverse. Twenty members are promoted to the fellowship, the annual average being a dozen; but it should be remembered that last year the list proposed by the Council was too illiberal for the most illiberal of all the corporations, and the Fellows refused to pass it, so that last year no Fellows were made.

The new list is therefore for two years, and consequently far below the average for numbers. It would be invidious to point to any one of those now selected as less worthy than the others. No one of them is perhaps absolutely undeserving of the honor, but it is rather hard that older and more distinguished physicians should have had to stand aside while personal friends of the officials walk in. Probably some of the new names are quite unknown on your side of the water, while among those who have been passed by are many physicians whose names are "household words" in America.

OUR PARIS LETTER.

(From our Special Correspondent.)

EXPERIMENTS WITH THE COMMA-BACILLUS—CHOLERIZATION—A NEW EXTRACT FROM COCA LEAVES—THE MYDRIATIC PROPERTY OF HYGRINE—EXPERIMENTS WITH CAFFEINE AND THEINE—THE GLUCOSIDE OF BOLDO AS A SUBSTITUTE FOR COCAINE.

PARIS, May 1, 1885.

DR. FERRÁN, of Tortosa, lately read a paper at the Academy of Sciences, in which he gave an account of the cultivation of the comma-bacilli which are met with in such large quantities in choleric dejections, and also of the experiments that he had performed with them. Guinea-pigs inoculated with this virulent culture were not only not killed, but were rendered capable of resisting the doses which previously would certainly have killed them. The same effects were produced in different persons who had the courage to submit themselves to this dangerous experiment. From these facts the author considers himself justified in concluding: 1. The possibility of "cholerization" in man as well as in the guinea-pigs, by means of hypodermic injections. 2. That the prophylaxis of cholerization is obtained by means of injections of virulent quantities, or of gradually increased doses. But the question that here suggests itself is whether the microorganisms employed by Dr. Ferrán were really those that are said to be found only in cholera; and even admitting that they were, it is still a matter of doubt as to whether the comma-bacillus is the pathogenic element of the disease.

M. Héricourt, who has occupied himself a good deal with the question since the late epidemic, is not of this opinion, as he has endeavored to show in a communication lately made by him at the Academy of Sciences, and which may be summarized as follows:

1. That all waters, whatever their quality or origin, contain curved bacilli, among which the type described as cholerigenic are constantly found.

2. The curved bacilli as such do not exist in the air, but they are to be found there in the form of spores.

3. The presence of curved bacilli in the waters, and of their germs in the air, would explain how it is that they are to be met with wherever water is accessible to them, or where the air can deposit its dust. Their presence has also been detected in the intestinal dejections of simple diarrhœa, in dysentery and typhoid fever, as well as in the broncho-pulmonary secretions of the various diseases of the chest, from the simple catarrh to the tuberculous cavity, pus exposed to the air, human saliva, whether healthy or not—in fact, all substances capable of serving as nutriment to bacteria contain curved bacilli, and sometimes in much greater number than other bacteria with which they are found associated in these different media of culture.

4. These micro-organisms are strongly aërobied and are only to be found at the surface of these liquids.

5. In fine, they are the same which are met with in all secretions, whether normal or pathological, on the only condition that the latter has been in contact with

water in which curved bacilli are constantly found, or with the air which conveys the germs.

Since the discovery of the anæsthetic properties of cocaine by Dr. Koller, who, however, employed it only in ocular therapeutics, it has rendered immense service to general surgery, and even to medicine, but it is still only obtained at great cost. In order to make its use more generally applicable, chemists and druggists have endeavored to utilize the residue of the coca leaves, after the extraction of the alkaloid so much sought after, by subjecting the leaves to further coction, etc., and thus obtaining a second extraction of cocaine. During the process, however, it was found that instead of cocaine another substance was discovered, and this new substance is a derivative of hygrine which does not possess the same properties as those of cocaine. In applying this new substance to the eye under the impression that it was cocaine, Professor Panas found that it determined a great and persistent dilatation of the pupil, which effect was rather different from what he was in the habit of obtaining with the hydrochlorate of cocaine. Moreover, while cocaine, in addition to its mydriatic property, was a powerful local anæsthetic, hygrine was a powerful mydriatic, but did not possess any anæsthetic quality. The mydriatic property of hygrine was at least equal to that of atropine, the effects, however, lasting a much shorter time, and in trying the action of eserine, Professor Panas found that while this substance overcame the dilatation of the pupil produced by atropine, and only for a short time, it completely abolished the mydriasis due to hygrine.

Many attempts have been made to find a less expensive substance as a substitute for cocaine. Among other investigators, M. Laborde tried some experiments with theine and caffeine, with a view of ascertaining whether these alkaloids possessed the same anæsthetic properties as cocaine; but he was always disappointed, as their application to the cornea, even in a saturated solution, did not produce the least anæsthetic effect on that membrane. In connection with this subject, I may mention that Dr. Dujardin-Beaumetz considers that the degree of anæsthesia produced on the cornea by cocaine is the best test of its purity.

The glucoside of boldo is another substance proposed as a substitute for cocaine, and in some experiments with this substitute M. Laborde found that, in certain proportions, the ocular anæsthesia produced by it was as well marked and altogether comparable to that resulting from the application of cocaine.

Dr. Combes lately submitted a paper to the Academy of Medicine on the effects of morphianism on the teeth. The author observed that, when a patient had taken morphia for some time, dental caries set in so rapidly that it sometimes affects the whole set in one year. The caries was generally accompanied by the falling off of the hair. Dr. Combes offered no explanation for this state of things, but proposed as a remedy that the morphia injections should be gradually discontinued, hydrotherapy resorted to, and the local treatment should be that of caries of the teeth in general. The commission charged to report on the paper were of opinion that the dental lesions were the result of alterations in the function of nutrition similar to the gangrenous and suppurative processes observed in morphiamaniacs.

COPPER TESTS IN THE QUALITATIVE ANALYSIS OF SUGAR.

To the Editor of The Medical Record.

Sir: From the phraseology that my friend, Dr. Fowler, has used in his "Note on the Detection of Sugar in the Urine," in your issue of May 2d, I judge that he expects a reply from me, though it seems to be clear that after charging me with "one statement which is incorrect," he practically refutes this very charge in a subsequent paragraph. He objects, apparently, to my statement "that Trommer's and Fehling's methods are thoroughly satisfactory in most cases where sugar is present, though on the whole the latter is less apt to be misinterpreted;" the force of his opposition being chiefly directed against the satisfactory character of Trommer's test, which I have alleged. The answer to this charge appears, however, to be embodied in Dr. Fowler's own words, that "certain ingredients of the urine, therefore, probably the coloring matter, interfere with the reaction of Trommer's test, and the custom formerly was first to filter the suspected urine through animal charcoal, whereby it is deprived of all color, and will thus react perfectly well."

According to this admission, then, Trommer's test *is* satisfactory, so that we are in agreement upon the matter after all.

But Dr. Fowler wishes it understood that the proper way to avoid error is to employ the test under rules that he lays down, which, however, do not appear to involve any radical improvement over other modifications already in use. If the reader and Dr. Fowler will consult the ordinary books of reference on urinary analysis, it will be seen that "Trommer's test" is not a uniform one as to the strength of the ingredients, or as to the order, even, in which they are combined to make the test. Each person has, doubtless, formed his individual plan upon certain ideas of convenience that have occurred to him. Personally, I am in the habit of using a strong solution of the copper sulphate (℥j. to ℥j.). Others in my laboratory use it in the proportion of forty grains to the ounce. I use liq. potassæ, U.S.; others use liq. sodæ., U. S. I take twenty minims of the suspected urine, add to it four to five minims of the copper solution, when a dirty green deposit is observed, and I then add thirty minims of the liq. potassæ, agitate, and get a transparent Prussian blue solution. This method is usually successful in detecting sugar if present in abnormal quantity. I still call it *Trommer's method*, though it differs from that accredited to Trommer in some of the books. And I am not alone in regarding it as a highly satisfactory test. It is also extremely delicate, and will indicate sugar in the proportion of one grain to the ounce, and in the presence of a five per cent. solution of albumen—an amount of albumen that will make a nearly solid precipitate in the test-tube. I do not find that Fehling's test gives any better reaction under such circumstances.

There are fashions and traditions in medicine as in every other professional avocation, and we are now in the habit of extolling Fehling's test for qualitative analysis—and are forgetful of the objections to be placed against it. For instance, if we employ Fehling's solution, as put up in drug stores, it is known to throw down the sub-oxide of copper after standing awhile, through the decomposition of one of its organic constituents. As a result, some of us have been in the habit of keeping the three ingredients in separate vials, the solution to be made as required. But Fehling's solution is not always reliable, even if freshly made, for a urine that contains a large amount of uric acid will throw down the sub-oxide after some minutes' boiling; besides, tannic acid in saturated solution will do the same thing, and very promptly. In fact, the number of organic and other substances that can be made to throw down the sub-oxide of copper in Fehling's solution, after considerable boiling, is probably quite large. While, however, I urge these objections against Fehling's solution, I hold it in high estimation for the promptness and sharpness of its reaction. Still, in the hands of persons accustomed to Trommer's test, it is "thoroughly satisfactory in most cases." Where there is any doubt about a specimen, several tests should be applied, as a matter of course, and albumen and coloring matter, or both, can be removed by appropriate means. As a third test I should name that with bismuth. There is, unfortunately, much confusion in the minds of practitioners on the matter of sugar, but the error lies chiefly with the chemists, who have led the practitioners astray by

their experiments upon sugar as an abstract substance, rather than as an ingredient of a complex substance—the urine. There are some other points in Dr. Fowler's communication in which I might take issue with him, but I have made mention only of those that seemed of most practical importance. I am respectfully,

THOMAS E. SATTERTHWAITE, M.D.

50 EAST THIRTY-FIRST STREET.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 10, 1885, to May 16, 1885.

VOLLUM, EDWARD P., Lieutenant-Colonel and Surgeon. Granted leave of absence for three months, to take effect when his services can be spared by his Department Commander. S. O. 110, A. G. O., May 14, 1885.

SMITH, A. K., Lieutenant-Colonel and Surgeon; HAPPERSETT, J. C. G., Major and Surgeon; KIMBALL, JAMES P., Captain and Assistant Surgeon. To constitute a board of medical officers appointed to assemble at the United States Military Academy, West Point, N. Y., on June 1, 1885, to examine into the physical qualifications of the members of the graduating class and the candidates for admission to the Academy. S. O. 106, A. G. O., May 9, 1885.

MCKEE, JAMES C., Major and Surgeon. Sick leave of absence still further extended four months, on surgeon's certificate of disability. S. O. 105, A. G. O., May 8, 1885.

BROWN, JUSTUS M., Major and Surgeon. From Department of the East to Department of the Platte.

DEWITT, CALVIN, Captain and Assistant Surgeon. Ordered to Department of the East. S. O. 105, A. G. O., May 8, 1885.

CORSON, JOSEPH K., Captain and Assistant Surgeon. Leave of absence extended ten days. S. O. 109, A. G. O., May 13, 1885.

DE LOFFRE, A. A., Captain and Assistant Surgeon. Assigned to duty at Fort Sisseton, D. T. S. O. 46, Department of Dakota, May 4, 1885.

KANE, JOHN J., Captain and Assistant Surgeon. Leave of absence for seven days extended one month. S. O. 109, A. G. O., May 13, 1885.

CARTER, E. C., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 106, A. G. O., May 9, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 16, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

TREATMENT OF ACUTE EARACHE.—Mr. H. B. Hewetson, of Leeds, recommends the slow injection of "glycerinum acidum carbolicum" into the external auditory meatus as a remedy for earache. It invariably stops the pain if poured carefully into the meatus.

FOR PHOSPHATES IN THE URINE.—A good pill can be made with five grains of benzoic acid and one minim of glycerine. This is a convenient way for giving it in phosphatic deposits.

SPECIFIC MEDICATION FOR WHOOPING-COUGH.—Dr. C. R. Illingworth writes, in *The Lancet*: "I have found a popular remedy very efficacious in the treatment of whooping-cough. I refer to picked oakum, worn by the patient either round the neck in muslin or on the chest as a pad stitched to the underclothing. Locally I apply the glycerine of tannic acid with a laryngeal brush two or three times a day, and internally I prescribe one-, two-, or three-grain doses of chloral, one, two, or three minims of belladonna, one grain of alum, and one minim of carbolic acid, in syrup, every two or three hours. A liniment of turpentine, acetic acid, and yolk of egg is an excellent application for the chest, back, and neck, night and morning, with the liniment of belladonna added in the proportion of 1 to 7. In children of two years or more, I have applied carbolic acid and glycerine, in the proportion of 1 to 15, to the larynx with success, each application checking a paroxysm at once. With the above-mentioned treatment I cure the worst cases in from seven to ten days."

ACTINOMYCOSIS.—A specimen illustrating this disease was recently shown by Dr. T. E. Satterthwaite at a society in this city. It was obtained from a New Jersey cow.

KERATIN PILLS, now much advertised in German journals, are pills covered with a coating of keratin, which is insoluble in the gastric juice but readily soluble in the alkaline juices of the intestine.

APIOL.—This is a product obtained from parsley (*apium petroselinum*) and possessing therapeutical properties analogous to those of quinine. It is given in doses of fifteen grains to a drachm.

DR. EDWARD A. WHALEY, one of the most prominent physicians in Brooklyn, died at his residence in that city on May 14th. Dr. Whaley was born in Avon, N. Y., in 1827, and graduated at the College of Physicians and Surgeons in 1850.

AT A MEETING of the New York Ophthalmological Society, held on Monday, May 11, 1885, the following report, in regard to the death of Dr. E. T. Ely, was adopted by the Society and ordered to be placed on the minutes, and a copy sent to his family and to THE MEDICAL RECORD and the *New York Medical Journal*:

"The members of the New York Ophthalmological Society herewith record their deep sense of the loss they have suffered by the death of their late associate, Edward Talbot Ely. Doctor Ely was elected a member of this Society in 1876. He became Secretary in 1880, and discharged the duties of that position with exactness and ability. His contributions to the discussions of the Society were always well considered and of value. In all their relations with Dr. Ely, the members of the New York Ophthalmological Society found him an interesting companion and a worthy representative of scientific medicine, and while they deplore his untimely death, they felicitate themselves that he lived long enough to add something to the vast and ever-growing structure of human knowledge, and to leave behind him an honored name.

"D. B. ST. JOHN ROOSA,
DAVID WEBSTER,
JOHN D. RUSHMORE,
Committee.

"J. B. EMERSON, *Secretary.*"

UNUSUAL MANIFESTATIONS OF MALARIA.

By ANDREW H. SMITH, M.D.,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

THE term malaria will be used in this paper to denote a peculiar poison of telluric origin, whose typical action is manifested by periodical accessions of fever followed by intermissions or remissions, and which is more or less subject to the control of the class of medicines known as antiperiodics, and especially of quinine. Thus restricted, the term excludes the poisons which result from defective house drainage, or from overcrowding, or are in any way directly or indirectly of animal origin.

While the diagnosis of the usual manifestations of malaria, that is to say of frank intermittent or remittent fever, is easy, there are unusual or obscure manifestations of its poisonous action which are not so readily recognized. There are cases even in which the most experienced observer may remain in doubt as to whether the phenomena present are or are not due to malarial intoxication.

The doubt in these cases arises from the fact that there is no one symptom pathognomonic of malarial poisoning, and that it is only by the presence of a group of associated symptoms that the affection can be positively diagnosticated. If, then, some of the symptoms belonging to this group are absent, and if furthermore other symptoms not belonging to the group are present, it may not be possible to arrive at anything more than a probable diagnosis, about which equally competent observers may well differ.

Referring to the definition of malaria already given, it may be remarked that the cases in which fever is absent, or at least is a wholly subordinate factor, are so numerous that we cannot insist upon it as necessary in any given instance. A host of manifestations undoubtedly malarial and mostly of a neurotic character are not marked by a greater degree of fever than might fairly be considered symptomatic of the prominent condition present. This is especially true of intermittent neuralgia, which, even in its severest form, is often accompanied by no more fever than the pain itself might be expected to occasion. Still, if the thermometer is employed instead of relying upon other signs, we shall often obtain from it information as unexpected as it is valuable; and it is to be noted in this connection that in these cases internal temperatures alone are to be relied upon, as the vaso-motor disturbances so intimately associated with malaria render axillary temperatures utterly untrustworthy.

Periodicity is a much more reliable test of malarial influence. Indeed, if we leave chronic malarial cachexia out of view, I do not believe that malarial poisoning can be positively made out in any case in which periodicity is wholly absent. The assertion that this or that affection is "malarial," without even inquiring as to the existence of intermissions or remissions, is too often a cover for ignorance or indolence. But the trouble is that, while in typical cases of malaria the periodicity is strikingly regular, in atypical cases it may be very irregular. Now in many affections not malarial irregular and even regular periodicity is a prominent feature, as, for example, in pyæmia and hectic fever. Hence, while the absence of periodicity is strong negative proof, its presence does not afford equally strong positive evidence. In cases in which there is but a single paroxysm the difficulty is still greater.

There still remains the diagnostic indication to be derived from the action of antiperiodic medicines. This, too, is beset by uncertainties, for, aside from the inevitable question of *post hoc* and *propter hoc*, quinine will not always put a stop to malaria, while it will relieve many morbid conditions not malarial.

In view of all these difficulties, the question may well be asked, How are we ever to know whether any but a typical case is or is not malarial? The answer to this is that, while in some cases there is no way by which we may arrive at absolute certainty, yet in most instances, by carefully weighing all the circumstances, we may come to a pretty definite conclusion.

The first point to be considered is that of exposure to the infection. If the patient has been for a lengthened period in a locality in which malaria is unknown, and if he has not suffered from malaria during a period of several years, the chance of its being a factor in an otherwise doubtful case would be almost nil. But the localities so free from paludial poison as not to afford a possible source of infection are, at least in this country, extremely rare: and with the nomadic habits of the American people, there are very few who do not expose themselves frequently to the chance of meeting the poison.

In this city, it is safe to say that the opportunity for infection is *always* present. The long period during which the poison may remain latent, extending, according to some writers, to one or two years, comes also into the account.

A history of former attacks lends great probability to the malarial character of a doubtful case. Susceptibility in the past argues susceptibility in the present, and conversely, one who has been often and freely exposed to malaria without becoming infected may be supposed to have a certain degree of immunity.

The manner of attack comes next in importance. If a patient in his usual health is suddenly taken ill, without any obvious cause, and if, after a period of four to twelve hours, the illness passes away, and especially if the latter part of the attack is marked by perspiration, the suspicion of a malarial causation in a case not otherwise explainable is warranted, even before a second attack.

The attack may have any one of a vast variety of forms, and may simulate almost any known disease; still, its abrupt accession, its brief duration, and its sudden termination, taken together, will suggest the idea of a malarial paroxysm. A repetition of the attack, particularly if it occur at the same hour of the day, adds the element of periodicity to strengthen the suspicion.

The effect of antiperiodic medication may aid materially in the diagnosis of doubtful cases. But the result must be promptly attained, else we shall be exposed to the danger of mistaking the simple tonic effect of the remedy for a specific antiperiodic action.

A neuralgia which yields promptly to one or two full doses of quinine would in so far be liable to the suspicion of a malarial parentage, while one that requires a long course of the drug for its removal is more likely due to an atonic condition, not at all connected with malaria.

Enlargement of the spleen is tolerably constant in malarial paroxysms, and when present aids materially in deciding the nature of an otherwise doubtful attack. But it is sometimes absent, or at least so slight in extent as to leave room for doubt as to its having any real significance, for slight splenic enlargement will take place whenever, from any cause, there is the least hindrance to the portal circulation.

Although some authorities have attached a good deal of diagnostic importance to certain appearances of the tongue, yet, beyond the fact that the organ is apt to be somewhat œdematous, there is nothing in its condition which can be considered distinctive of malaria.

The following cases which have occurred in my practice are brought forward partly to illustrate various forms of malarial manifestations and partly to show the difficulties which may lie in the way of diagnosis :

Case I.—Some seven or eight years ago, when the tunnel was being constructed in East Forty-second Street, I was called in consultation to see a child living in that vicinity which was supposed to be suffering from acute meningitis. There was a high degree of fever, injection of the conjunctivæ, wild delirum, and vomiting. Another child in the same family had died a few days before with precisely similar symptoms, and after an illness of only a few hours.

I was struck, however, by the fact that while the symptoms never fully intermitted, there were periodical exacerbations, and in view of the prevalence of malaria in the vicinity, I advised that a large dose of quinine be given by the rectum, the stomach being too much disturbed to retain it. The effect was immediately beneficial, and by following up the treatment the child promptly recovered.

In this case congestion closely simulating meningitis was excited by the malarial poison. Where head-symptoms of this character are promptly relieved by quinine, I think there can be no doubt as to the presence of malaria, for in a case of acute meningitis a large dose of quinine could only intensify the symptoms.

In the next case the result was not so satisfactory, although some degree of betterment resulted from the quinine, and I am in doubt as to the extent of the rôle played by the malarial element.

Case II. was that of a child in which a diagnosis of tubercular meningitis had been made. There was intense headache, corrugation of the forehead, photophobia, vomiting, and flatness of the abdomen with constipation. But the headache was confined to the right frontal region and was periodically worse, the pupils were symmetrical, the vomiting was not projectile, and the abdomen, though empty and collapsed, was not retracted and hard. The temperature as taken morning and evening was normal. When I saw the child no urine had been passed for twenty-six hours and percussion showed the bladder to be empty. There was an abscess of the hip-joint which had been discharging for six months. This fact, together with the suppression of urine, made me suspect uræmia depending upon surgical kidney, and which might account for the headache and vomiting. But hot applications and dry cups to the kidneys soon brought on a flow of urine, which when examined gave no evidence of renal disease.

By this time the third or fourth day of the attack had been reached, and it was noticed that there was a marked exacerbation of the symptoms each day at about the same hour, half-past two in the afternoon. I now requested that the temperature should be taken at 3 P.M., as well as in the morning and at evening, and the result showed a decided febrile accession which lasted two or three hours. I should have mentioned that there was at all times an extreme irregularity of the pulse both as to force and frequency, about as lawless a pulse as it is possible to imagine, but there was no cardiac murmur. I now became impressed with the conviction that the case was essentially malarial, and at my suggestion a liberal dose of quinine was given. The effect was very marked. The child soon ceased to complain, declared that he was "all right," and joined readily in the conversation of his fellows. The improvement in this respect, however, was not maintained to its full extent, the headache recurring in a milder form in a few hours. But the most singular fact was that persistence in the use of quinine brought about within twenty-four hours a complete restoration of the regularity of the heart's action. Nevertheless the patient continued to lose strength, and eventually convulsions set in, strabismus occurred, and death took place. An autopsy could not be obtained. The irregularity of the heart's action in this case and the suppression of urine will be referred to in another connection.

Case III.—In November last I was called to see a lad ten years of age living in a notoriously malarial region. He had been slightly ill in an indefinite way for ten days, had lost his energy, was dull and listless, and complained of feeling weak. His appetite remained fairly good, but his tongue was white and pasty. He was better and worse by turns, but his mother had not observed any well-defined periodicity.

The first touch of the finger to the pulse showed an excessive irregularity of the heart's action, both as to rhythm and force, and on auscultation a loud, harsh systolic murmur was found, confined to a small space about the apex and over the left ventricle. The cardiac impulse was felt in the normal situation, and the area of cardiac dulness was not increased.

The spleen was enlarged to twice its natural size.

Full doses of quinine were administered, and in twenty-four hours the action of the heart had decidedly improved. Within ten days no trace of cardiac trouble remained, the health in every particular was restored, and the boy has continued perfectly well up to the present time.

Here, as in the preceding case, we have a disturbance of the cardiac innervation, causing altered rhythm of the heart, and in addition in this case such inequality in the action of the papillary muscles as to result in very decided mitral regurgitation. The cardiac symptoms in Case III., and the effect of quinine upon them, go to reinforce in my mind the conviction that Case II. was largely influenced by malarial poisoning.

Case IV.—I have recently had under my care a delicate girl, twelve years of age, who had whooping-cough rather severely, and in about the fifth week was taken with measles. The temperature at the outset reached 105.5° ; the eruption was scanty. During the first four or five days there were accessions of high temperature from time to time without any regular periodicity, the fever nearly disappearing in the intervals. A severe bronchitis followed, with a little lobular pneumonia at the base of each lung. The temperature during the day was seldom above 101° or 102°, but each morning at about three o'clock it ran up to 104° or 105° ; the cough became very violent and continuous, and very large quantities of muco-pus were expectorated. Three or four hours after, the temperature fell two or three degrees, the cough became only an occasional hack, and the expectoration nearly or quite ceased. The spleen was found to be slightly enlarged.

Constantly increasing doses of quinine were given, but it was not until eighteen grains were administered daily that the morning accession of fever was in any measure controlled. It was finally entirely subdued, and with it the excessive cough and expectoration. From this time the patient improved rapidly and convalescence was soon established.

In this case the malarial influence seemed to expend its force upon the pulmonary mucous membrane, inducing hyperæmia and excessive secretion.

The next case presents some analogous features.

Case V.—Mrs. ——, living in a locality noted for malaria, had a slight chill at half-past two in the afternoon, accompanied by pain under the right shoulder-blade.

Careful examination of the lung two hours later gave only a negative result. At the same hour on the following day, the fever returned with great violence, the temperature reaching 106°. There was intense pain throughout the abdomen, with severe purging and vomiting, and great prostration. There were abundant mucous râles in both lungs, but especially in the right, where slight dulness on percussion could be made out. Bronchial breathing if present was masked by the râles. At one time the patient was nearly moribund. Thirty grains of quinine were given by the rectum (the purging having ceased) every three hours until ninety grains had been taken. There was a prompt fall of temperature and an improvement in all the symptoms. The following morning the physical signs indicated pneumonia, limited to the right upper lobe. The patient was kept fully under the influence of quinine for several days; the temperature remained moderate, resolution took place at the usual time, and convalescence was complete.

Here we have apparently a malarial chill coinciding with the chill of approaching pneumonia, and followed at the same hour next day by a pernicious paroxysm, the force of which fell upon the lungs and the abdominal viscera.

Case VI.—Some years ago I was called in great haste early one morning to see a little girl two years of age, who had been brought, as usual, to the bed of her father and mother, and while playing with them suddenly became unconscious, and passed into a state resembling catalepsy. I found her lying with her eyes open, her face having a natural expression, respiration and pulse normal, temperature very slightly raised. But for half an hour or more no effort could rouse her to any sign of consciousness. When at last she awoke from this singular sleep she was a little feverish, but by the afternoon she appeared as if nothing had happened.

The following morning, at precisely the same hour, all the phenomena of the preceding day were repeated, to be followed by the same feverishness and malaise. I then considered that the attacks were caused by malarial poisoning and made every effort to get the system fully under the influence of quinine before the next period should arrive. In this I was successful, and there was no return either of the cataleptic state or of the febrile paroxysm.

I judge this case to have been one of malarial poisoning, because I can conceive of no other cause which would act so suddenly and so transiently, and because of the two paroxysms occurring at the same hour on two successive days. To these reasons may be added the failure of the paroxysms to recur after the system had been brought under the influence of quinine.

The following case I cannot explain, except on the supposition that it had a malarial origin:

Case VII.—A child, aged sixteen months, a patient of Dr. Cosgrave (who called Dr. Bruce in consultation), was put to bed in his usual health at seven o'clock in the evening, and soon fell into his usual natural sleep. At nine o'clock the mother's attention was aroused by hearing him breathe in a peculiar manner, and on attempting to rouse him, she found him comatose. Dr. Cosgrave was immediately summoned, and found the child entirely unconscious, the chest full of mucous râles, the churning of which could be heard through the open door in the next room. The face was pale, lips livid, both eyes turned outward and upward, pulse 160, temperature 104½°. I saw the case at ten o'clock. The symptoms had not changed, except that the respiration had become gasping and very infrequent, so that each breath seemed as if it might be the last. Although the case appeared hopeless, it was determined to try the effect of hypodermic injections of brandy. Ten minims were given, and in fifteen minutes the dose was repeated with the addition of one drop of tincture of digitalis. The respirations began to increase in frequency, the lividity of the lips became less marked, and the radial pulse, which had been lost, returned. The brandy and digitalis were continued, and the child was gradually restored to consciousness. It being considered that the case was malarial, quinine was administered liberally. The bronchitis so suddenly developed continued, but ran through a favorable course, and in a week the child was fully convalescent.

In this case the brain and the lungs received the brunt of the attack through paralysis of their vaso-motor nerves. From this the brain recovered when the paroxysm had spent its force, but the lungs were left with a severe acute inflammation of the bronchial membrane.

In the second case cited, among the features which I considered malarial was a suppression of urine for twenty-six hours. In the following case the suppression continued five days.

Case VIII.—A young servant girl, for whom I prescribed while in the country last summer, and who was of a malarial habit, had a chill, followed by fever and headache, every morning at ten o'clock. She was a very intelligent girl, and very determined, and insisted upon continuing her work. During this whole period there was not a drop of urine passed, if her statement can be credited. A few large doses of quinine disposed of the chills and the anuria together.

In regard to this case it may be said that there are many instances on record in which hysterical anuria persisted much longer than the anuria in this case. There may have been an hysterical element in this case, also, though the usual emotional symptoms were wanting. But if so, it was intimately associated with the chills, and ceased when they were broken up.

SOME OF THE IRREGULAR MANIFESTATIONS OF MALARIA.[1]

By L. EMMETT HOLT, A.M., M.D.,

PHYSICIAN TO THE NORTHWESTERN DISPENSARY; INSTRUCTOR IN THE NEW YORK POLYCLINIC.

In the study and discussion of a subject like the one chosen for this evening, there are two errors into which we may fall. The first is, to attribute to malarial poisoning all of that vast number of ill-defined ailments which cannot properly be classed as belonging to any one of the organs. The second is, never to admit the diagnosis of malaria unless a distinct history of a typical paroxysm is found to be present. This latter position, it seems to me, is just as wide of the truth as the first one stated, although it may not be so commonly taken.

Malaria in one form or another is just now the popular disease. It is a convenient term for the layman to apply to his indisposition, and, as a rule, he feels quite gratified to have his physician confirm his diagnosis, which the latter too often does without any well-grounded reasons. In medicine, as in most other things, we find what we look for. The malarial bias is as easy to acquire as it is hard to shake off. For, when one has watched cases, with symptoms pointing to grave disease of the brain, lungs, or kidneys, when he has used the ordinary therapeutic measures without the slightest effect, and then seen how all difficulties were cleared up, when malaria was found as an underlying or modifying cause, it is hard for him not to believe that almost any group of symptoms may be produced by malaria.

Still the profession has a right to be sceptical regarding many symptoms put forward as masked intermittents. Something more than mere dictum must be offered. What then shall we insist upon as the criteria of malaria?

This is the most difficult point to settle, and the one upon which, it seems to me, the whole discussion hinges. I remember that Dr. Janeway called our attention, several years ago, in Bellevue Hospital, to the fact that cases

[1] Read before the Section of Practice of the New York Academy of Medicine, May 19, 1885.

of typical intermittent fever *originating* in New York City were exceedingly rare. Those seen here would, on close questioning, be found to have contracted the disease in New Jersey, Long Island, or in the South. This is an important point, which should not be lost sight of. Among over three hundred cases of malaria of which I have records, there is scarcely a single exception to this rule. Those who insist on the presence of the regular chill, fever, and sweat, will see but little malaria in New York.

In my own cases I have been rarely willing to make a positive diagnosis of malaria unless at least two of the following conditions were present: 1, Periodicity in the symptoms; 2, prompt curability by quinine; 3, enlargement of the spleen. I have placed them in the order of their importance, as I have come to regard them.

There might be also added, the presence of fever, as determined by careful thermometric observations made morning and evening. Taken alone, of course, this symptom amounts to little or nothing.

Periodicity of malarial symptoms, as we see them in New York, is by no means always so marked as at once to be apparent. It may require very close observation on the part of the physician to establish this fact.

To the therapeutic argument, from the effect of quinine, I am inclined to give a good deal of weight, particularly in those cases where other measures have signally failed, and where prompt improvement is noticed to follow the use of the drug. Although quinine was much vaunted a few years ago in pneumonia, erysipelas, tuberculosis, septicæmia, and other allied febrile diseases, further experience has, I think, shown conclusively, that it is of little value in reducing temperatures not malarial. In my own cases with high temperature, in which the exhibition of quinine in full doses was without result, I have found, I think, invariably, that malaria was neither the primary cause, nor a potent factor in producing the fever.[1]

The question of splenic enlargement is a difficult one to settle in many cases undoubtedly malarial. In nearly all the acute, severe cases it is, I think, demonstrable. In a large number of those of a milder type, I have been unable to satisfy myself of its presence, especially in first attacks; while most of the cases of chronic malarial cachexia show a marked degree of enlargement.

Besides these fundamental symptoms, if we may so term them, there are others which are highly suggestive, and which may lead us to look for a malarial element in cases where it might otherwise escape us. Among them may be mentioned: 1, Marked drowsiness; 2, headaches, usually supra-orbital; 3, anæmia and cachexia; 4, vertigo; 5, digestive derangements, anorexia, thickly coated tongue, and constipation.

Drowsiness, heaviness, and apathy, especially when coming on at some regular time in the day, usually toward evening, are most characteristic symptoms in children. Constipation I have found present much oftener than diarrhœa, although several very striking cases of the latter, in malarial cases, have fallen under my observation.

In general, however, it is rather by the combination of symptoms, than by the invariable presence of single ones that a diagnosis is reached.

A peculiar form of incontinence of urine I have seen associated with so many cases of malaria as to convince me that it was not a coincidence. The patients were children, from seven to twelve years of age, who had, as a rule, never before suffered from this affection. The incontinence was only present during the day. It seemed to depend upon extreme vesical irritability. Micturition was very frequent, sometimes every fifteen minutes, and unless immediate response was made to the call, the clothing was wet. Examination of the urine threw no light upon these cases. The incontinence did not outlast the malarial symptoms.

Periodical attacks of gastralgia may occur with fever and other symptoms of malarial poisoning, or may constitute the principal complaint of the patient. The pain seems to have no relation to the taking of food. It is often associated with epigastric tenderness.

General cutaneous hyperæsthesia has been prominent in several cases. The patients have usually complained of being "sore all over." Handling the muscles often gave so much pain that they cried out. Locomotion seemed to be painful. The hyperæsthesia was more marked in the thighs and legs than elsewhere. It occurred in the mild rather than in the severe cases.

I have written elsewhere[1] regarding pulmonary symptoms occurring with malarial fever, which may very closely simulate pneumonia, both in its symptoms and physical signs. The breathing is often more rapid even than in pneumonia; the temperature is equally high or higher, and the invasion is just as acute. The severity of the symptoms mentioned is strikingly out of proportion to the amount of general disturbance which the patient shows. If the temperature is carefully watched for twenty-four hours, a marked remission will always be found to occur, if the case is one of malaria; and with the fall in the temperature the pulmonary symptoms greatly subside or disappear altogether.

In a former paper[2] I have referred to six cases of spasmodic asthma which were supposed to be due to malarial poisoning. Although constantly on the lookout for further clinical evidence in support of this view, I am compelled to say, in the light of a much wider experience, that it has been wanting. This leads me to believe that I may have been mistaken, and that the connection between the asthmatic attacks and malaria was not so close as I was led to think.

As additional evidence to that which has been lately adduced, of a connection between malaria and diseases of the ear, two cases of severe otalgia occurring with what was in other respects an ordinary malarial attack deserve to be mentioned. Both were in children and seemed to be purely neuralgic.

A malarial manifestation in which I have been particularly interested of late is spasmodic torticollis. In going over my records for two and a half years I have found notes of twenty-one cases of torticollis, excluding those dependent upon bone disease. In seven the symptom was accounted for by cold, scarlet fever, measles, or traumatism. In the remaining fourteen, evidence of malaria, to my mind satisfactory, existed. In eight distinct periodicity was observed. The symptom would come on every day about the same hour, generally toward noon, and last until the patient went to bed. On rising the following morning, the neck would either be perfectly free, or only a little stiffness was left. In the remaining six the malarial symptoms accompanying the torticollis were quite as marked, but they were not under sufficiently close personal observation to enable me to settle positively the point of periodicity. These cases have been treated in a great variety of ways in order to settle beyond a doubt the fact of their malarial character. Generally I avoided giving quinine for three or four days until I had a chance to observe recurring paroxysms. In some of the least severe I withheld quinine altogether, and found that they gradually recovered spontaneously. The more marked ones showed a strong disposition to recur with the same severity until quinine was given. The universal experience was prompt and permanent relief by quinine, no matter whether the cases were of two days' or ten days' standing. Local applications were tried in most of the cases, but were useless. There was great similarity in the cases, though all degrees of severity were seen. All came on with quite an abrupt invasion; all were walking cases, with a temperature, I think, never

[1] Does Quinine Abort Pneumonia? New York Medical Journal, February 21, 1885.

[2] Malaria in Children, American Journal of Obstetrics and Diseases of Children, Nos. i.-iv., 1883.

higher than 102°. Two or three complained of pain about the neck, but in most of the cases this was only present on an attempt to rotate the head actively or passively.

23 Park Avenue.

HYDROCHINON, A NEW ANTIPYRETIC.

By FRANCIS KINNICUTT, M.D.,

physician to st. luke's hospital, new york.

Medical literature has been enriched during the past two years by a number of important papers on the antipyretic powers of several coal-tar derivatives. Kairin, antipyrin, thallin, successively have been brought into notice as efficient antipyretics, and within the past several months hydrochinon has been added to this list.

Hydrochinon is known to chemists as a dihydroxylbenzole, with the formula $C_6H_4(OH)_2$, and is isomeric with resorcin and brenzcatechin. It crystallizes in rhombic, colorless prisms, is slightly soluble in water, easily so in alcohol and ether, and has a sweetish, not unpleasant taste. Its physiological action was first determined by Brieger,[1] in the Physiological Institute in Berlin, in 1879. Frogs and rabbits were used in his experiments. In the former, 5 c.ctm. of a 1–1,000 solution of hydrochinon produced convulsions after some minutes, with death in four and a half hours. Warm-blooded animals bore relatively larger doses. Quarter-gramme doses were given to rabbits with no effect. A half gramme produced slight convulsions after a half hour, with subsequent recovery; while three-quarters of a gramme caused general clonic convulsions, dyspnœa, dilatation of the arterioles, an increase in the salivary and lachrymal secretions, diminution of reflex irritability, a rise in temperature of 2.7° F., death in one and a half hours. Convulsions were produced in a larger rabbit by a gramme dose, but with subsequent perfect recovery. The urine was darkened during its use, but contained no free hydrochinon. The toxic effects of hydrochinon closely resemble those of phenol and comprise stupor, collapse, muscular tremors followed by severe reflex convulsions which increase in intensity, dyspnœa, subsidence of the convulsions, sudden death.

Brieger also was the first to test the effect of hydrochinon upon human beings. He found that an almost unfailing and marked antipyretic effect could be obtained by doses which were unattended with any injurious results. In the *Berliner klin. Wochenschr.*, 1884, No. 29, Dr. Siefert[2] publishes an interesting clinical paper on the results obtained by him in thirty-eight cases of pyrexia treated with hydrochinon; of these, fifteen were cases of typhoid fever. He found that single doses of fifteen grains caused a fall of temperature of 1.8° to 3.6° F. with sweating; in some cases 5° to 6° F.; that the lowest point was reached at the end of two or three hours; that the temperature then gradually rose during another hour, with sometimes slight shivering, to its former height. No disturbing symptoms of any kind, with the exception of very occasional vomiting, were observed during its administration. In children the results obtained were quite as favorable as in adults.

During the past three months I have been able to make a careful study in my wards at St. Luke's Hospital of the effects of hydrochinon. The points which I planned personally to ascertain were its effects upon the body in health, upon the pyrexia of different diseases, the degree and duration of its effect, the most efficient mode of administration, and, finally, the contra-indications, if any, to its employment.

To the co operation and labor of Drs. Sherman, Mabbot, and Tieman, the very efficient house staff of the hospital, I am largely indebted for the interesting facts which I have been able to obtain. The above gentlemen volunteered to ascertain the effect of the drug upon themselves in a state of health. Ten and twenty grain single doses produced no appreciable symptoms. The pulse, respiration, and temperature were unaffected. A single dose of forty grains, taken by Dr. Sherman, was followed in ten minutes by a feeling of slight fulness in the head and slight dizziness, wholly disappearing in fifteen minutes. No appreciable diaphoresis occurred in any instance.

Its elimination by the kidneys was tested by careful urinary analyses, with results which will be mentioned presently.

Effects upon the pyrexia of different diseases.—The number of cases treated was fifteen, and embraced three of pulmonary tuberculosis, one of general tuberculosis (autopsy), two of pleurisy with effusion (with high temperature curve), three of acute lobar pneumonia, one of acute inflammatory rheumatism, one of acute rheumatism with pleurisy, one of intermittent fever (malarial), one of puerperal septicæmia and pyæmia, one of facial erysipelas (with high temperature curve), one of pelvic cellulitis.

Fifteen and twenty grains were the standard single doses adopted. A marked reduction of the temperature was obtained, *without exception*, in all the cases after each administration of the above dose. By repeated observations it was ascertained that after a single dose the temperature begins to fall, as a rule, within fifteen minutes.

The minimum level is reached in two to two and a half hours; the temperature then again gradually rises during another hour to two hours to its former height. The degree of reduction was observed to vary somewhat, being dependent, apparently, rather upon individual idiosyncrasies than upon the nature of the disease. The minimum fall obtained was 1.5° F., the maximum 5.2° F.

The following tables, among many others carefully recorded, well illustrate the above points:

Case I. General Tuberculosis.—Female, aged thirteen.

Time.	Temperature.	Pulse.	
4.00 P.M.	103.2°	132	Hydrochinon, gr. viij.
4.19 P.M.	101 8°	130	
4.34 P.M.	101.5°	129	
4.50 P.M.	101.2°	124	
5.05 P.M.	100.8°	120	
5.25 P.M.	99.9°	120	
5.35 P.M.	99.4°	118	
6.03 P.M.	98.8°	118	
6.20 P.M.	99.6°	123	
6.38 P.M.	100.2°	125	
6.55 P.M.	101.1°	...	
7.30 P.M.	103.8°	144	

No sweating, nausea, or vomiting; no chills or chilly feelings.

Case II. Facial Erysipelas.—Male, aged seventy.

Time.	Temp.	Pulse.	Resp.	
11.33 A.M.	104.0°	108	24	Hydrochinon gr. xx.
11.50 A.M.	103.5°	100	24	
12.10 P.M.	101 6°	88	22	
12.40 P.M.	101.0°	83	18	Sweating.
1.10 P.M.	100.8°	84	18	
1.40 P.M.	101.3°	106	18	Slight chill.
2.10 P.M.	102.4°	...	..	

No nausea or vomiting.

Case III. Puerperal Septicæmia and Pyæmia.

Time.	Temperature.	
5.40 P.M.	103.6°	
7.00 P.M.	100.2°	Sweating.
8.00 P.M.	98.5°	
9.00 P.M.	99.0°	
10.00 P.M.	100.6°	Slight chill.
11.30 P.M.	104.0°	

No nausea or vomiting.

[1] Archiv für Anat. und Physiol., 1879, Supplement-band, p. 67.

[2] Dr. Siefert's paper, so far as I am aware, is the only one thus far published on the clinical use of the drug.

Neither nausea nor vomiting occurred in any case during the use of the drug. Moderate sweating was observed in the majority of cases accompanying the fall of temperature; it was rather a relief than a source of discomfort to the patient. In the case of puerperal septicæmia and in one case of pneumonia, it was profuse.

In the case of general tuberculosis, it was on no occasion present. A slight chill occurred in two cases during the rise of temperature, following the minimum level reached. Slight chilly feelings were described by other patients on close questioning. They were wholly absent in two cases in which six hundred and two hundred and thirty grains, respectively, were given in the course of the disease. There was an entire absence of the disagreeable symptoms (fulness of the head, dizziness, ringing in the ears, etc.) accompanying the use of large doses of quinine and the salicyl compounds. The effect of hydrochinon upon the pulse was, in a measure, proportionate to that upon the temperature; its frequency constantly diminished with the fall of temperature, and its quality apparently improved. The number of the respirations fell coincidently with the temperature and the pulse, in cases where their frequency evidently was dependent upon the pyrexia alone. In cases of pulmonary disease the respiration was affected slightly, if at all.

The most efficient mode of administration.—Single doses of fifteen to twenty grains of hydrochinon by the mouth were found amply sufficient to produce the effects above described. In cases of pulmonary tuberculosis, such a dose administered at the time of the usual afternoon rise of temperature readily controlled the pyrexia, with great relief to the patient.

In cases where there was a tendency to a continuously high temperature, three or four single doses were given in the course of the twenty-four hours, with the effect of maintaining the temperature at a moderate level. The latter method of administration would seem suitable in cases of typhoid fever. At this season of the year our hospitals contain few cases of this disease, and I, therefore, am unable to report any personal observations bearing upon this point.

The comparative effect of the drug given by the mouth and rectum was observed. It was found that doses of thirty grains, given in a little starch-water in the form of enemata, were required to produce the results obtained from fifteen grains administered by the mouth.

Contra-indications to the use of hydrochinon.—From the fact that no unpleasant symptoms occurred during its use in many and widely differing pathological conditions, I am disposed to believe that the contra-indications to its employment must be exceptional. With the doses used there was never any indication of cardiac depression; on the contrary, the quality of the pulse seemed rather to improve coincidently with the diminution in its frequency.

The effect of hydrochinon upon the urinary excretion was very carefully observed by the gentlemen of the house staff, in their own persons, and in the patients under treatment. After a single dose of the crystals, the urine, when voided, was normal in color. It assumed a greenish-brown, often a dark-brown hue after standing for twenty-four hours. A similar dark discoloration was observed at *the time of voidance*, in the urine of patients kept continuously under the influence of the drug. It was found that nitric acid alone and nitric acid with heat, used as in testing for albumen, could be relied upon for detecting the presence of the products[1] of hydrochinon in the urine. With nitric acid, an orange-red color appears at the line of junction of the acid and the urine in the test-tube; above this, layers of green and purple successively. On the additional application of heat, a dark—almost black—cloud appears in the upper levels of the column.

[1] Braumann and Preusse have shown that the discoloration of the urine is due to the presence of higher oxidation products of hydrochinon. Archiv. für Anat. und Physiologie, Phys. Abtheil, 1879, III. und IV. Heft, pp. 245-249.

Elimination of hydrochinon products, after single doses of twenty grains, was ascertained to begin in from thirty to forty-five minutes, and to continue for about sixteen hours. A gradual diminution and increase of the sulphates corresponded with the increase and subsidence of the products of the substance in the urine.

I am unable at present to give accurate results of the analyses for urea.

Neither albumen nor casts were ever detected in urine which previously had been free from them.

From my experience with the use of hydrochinon I would draw the following conclusions:

1. That in hydrochinon we possess a new and most efficient antipyretic.

2. That its use is apparently unattended with any injurious effects.

3. That the antipyretic effect of single doses is comparatively temporary, resembling in this respect that of kairin, thallin, and antipyrin; that the maintenance of moderate temperatures in hyperpyretic conditions can be safely obtained, however, by repeated doses.

4. That while apparently without effect in arresting a specific disease-process, its employment is conservative and productive of a marked amelioration of many of the symptoms incident to high temperatures.

5. That with our as yet limited experience with the drug, it should be given prudently and its effects carefully observed.

IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS?

When Should the Operation be Performed?

By JOSEPH E. WINTERS, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, UNIVERSITY CITY OF NEW YORK.

Having been honored in The Medical Record with a criticism on my article on the above questions, I desire to re-state some points which seem not to be clearly understood.

Early or late operation, and the danger of the operation, seem to be the two burning questions. We will first consider the former.

How does prolonged croup influence the pulmonary circulation? When there is obstruction at the rima glottidis, a limited supply of air enters the lungs with every inspiration, the lungs are less expanded, the aspiration force is lessened, the air in the lungs and bronchi becomes rarefied, and the blood not finding the same resistance in the air-cells and small bronchi, enters more freely and circulates more slowly than it does when sufficient air enters the lungs and there is proper expansion and retraction of these organs. The blood in the pulmonary capillaries is imperfectly aërated, and becomes charged with carbonic acid, producing increasing distention of the capillaries; carbonized blood tending to accumulate in the capillary system.

This slowing of the circulation in the pulmonary capillaries leads to stasis, splenization, and œdema. The blood accumulates, therefore, in the trunk of the pulmonary artery, in the right heart, and in the systemic veins. The cutaneous capillaries become engorged, producing the well-known bluish tint of the external surfaces, especially the violet hue of the lips and nails. The bronchial veins through the vena azygos on the right side, and the superior intercostal on the left, opening respectively into the superior vena cava and the left innominate, early feel the influence of this retrograde engorgement, and this causes serous exudation into the bronchial tubes. This exudation impedes the entrance of air to the air-cells, and then follow all the well-known changes which occur in broncho-pneumonia. In contiguous lobules, and especially at the upper and anterior portions of the lungs, vicarious emphysema occurs. These emphysematous portions of the lungs are anæmic. But these are secondary, compensatory changes.

At that part of the lungs where air reaches, there is but little blood to act upon, and where there is blood, air cannot penetrate. When the thorax is opened the lungs do not collapse, owing to vicarious emphysema, and because the air in the bronchi is prevented from escaping by the mouth, by the large quantities of secretion in them. For this reason the *superficial* observer at once concludes that he has to do with emphysema pure and simple; whereas a *very* little reflection would convince one of his error. Where there is prolonged croup, congestion of the lungs is inevitable.

Dr. Rupp, quoting Dr. T. A. Barker to prove that laryngeal obstruction does not produce pulmonary congestion (be it marked that this was of a case of intralaryngeal growth), says:[1] "The child died asphyxiated, presenting the symptoms of croup."

The child having been leeched, tartar emetic and hydrarg. cum creta administered, blisters applied, and mercurial inunctions used, Dr. Barker's exact words are:[2] "Each report, on November 9th, 10th, and 11th, states he had improved; the breathing was easier, the respirations remained about twenty-two in the minute, but were less labored, and there was an *interval* between expiration and inspiration, the pulse ranging from 80 to 95; but on the 12th, after a restless night, he died *very* suddenly. The statement of the sister of the ward was that he appeared much better when she had seen him on the night of the 11th; and the night-nurse asserted that, although he had been restless, there had not been more *wheezing, cough*, or *difficulty of breathing* than she had noticed on former nights." (Italics mine.)

Dr. Barker says *nothing* about the child's "dying asphyxiated, presenting the symptoms of croup."

When, in the vain and delusive effort to prove a *theory*, the truth is put to such a strain as this, every statement must be suspected; and this feeling is strengthened by the misquotations from my own article.

Observe Dr. Barker's comment: "It is almost superfluous to allude to the mischief which may arise in other parts when the operation [tracheotomy] is needlessly or unavoidably delayed; so that whatever may be the immediate result, the operation fails to give permanent relief. The chief danger, of course, is that of congestion of the lungs."[3]

Dr. Fuller is quoted as supporting the theory of anæmia of the lungs. Let us examine his post-mortem records. These will include every autopsy recorded by Dr. Fuller. Cases 1 and 2 recovered. Case 3 died soon after operation.[4] "The lungs were very œdematous, and the lower lobes on either side hepatized. The bronchial mucous membrane was vascular throughout, and was covered to a great extent by the same sort of soft albuminous matter which existed in the trachea. Many, even of the smallest bronchi, especially those leading to the inflamed and hepatized portions of the lungs, were full of this deposit." Case 4 died about twenty-four hours after operation. "The lungs were congested, and the smaller bronchi contained a good deal of thick mucus, mixed with blood." Case 5: death twenty-six and a half hours after operation. "The bronchial lining membrane congested and covered with thick mucus, and the right lung in one part passing into the early stage of red hepatization." Remarks by Dr. Fuller as to the *influence of delay in operating:* "Each minute that is lost afterward is so much against the patient's recovery; for with approaching suffocation the strength fails rapidly, and passive congestion of the lungs takes place." This is very bad support for those who would fain find anæmia of the lungs resulting from neglected croup!

The citation of the case from Bretonneau, with its *attendant treatment*, to bolster up the theory of anæmia of the lungs, is—pardon the expression—silly twaddle.

[3] Ibid., p. 231. [4] Ibid., vol. xl., pp. 43 et seq.

Passavant has been quoted in The Record, with protective caution, however, on the changes in the pulmonary circulation in untracheotomized croup. He says:[1] "The cause of the excess of blood in the lungs of croup patients is exactly the same as on the skin to which cups are applied. The consequences are bulging of the mucous membrane toward the rarefied space, overfilling of the capillaries, and consequent slowing of the circulation in the same, leading to stasis, splenization, ecchymosis, and increased secretion from the mucous membrane. The excess of blood in the lungs farther causes bloodstasis in right heart, filling up of the cervical veins, and livid countenance. Finally the hyperæmia of the lungs leads to pulmonary œdema."

To Niemeyer's pathology this is strikingly similar.

Hasse[2] says: "The lungs generally do not collapse, are dark-colored, turgid with blood, and occasionally exhibit isolated patches of inflammation."

It has been said, at the Pathological Society in this city, that anæmia followed instead of congestion, when the entrance of air to the lungs was partially prevented, and that this view "was certainly accepted by pathologists in general."[3] There are pathologists who seem to *accept* this view, but there is not one who *describes such changes*.

I would strongly urge those who would not feed upon blind illusions, but who are still trying to possess themselves of the *theory* of prolonged croup producing pulmonary anæmia, to read Niemeyer on "Croup," and Steiner in "Ziemssen," with comments on Niemeyer's article.

If the sage advice of Morgagni, "We should weigh, not *count* our cases" [italics mine], had been followed, the theory of anæmia of the lungs, with other equally preposterous and mistaken notions concerning croup and tracheotomy, would never have been concocted.

The following are a few additional authors who may be referred to as having found that croup leads to congestion of the lungs: Vogel, Oertel, Steiner,[4] Gerhardt, Bohn, Bartels, Bouchut, Stokes, Loomis, Watson, Cheyne, Copland, William Squire, Porter, Condie, Thomas King, Chambers, Henoch,[5] Tanner, Evanson and Maunsell, Cohen, Parker, Johnson, J. Lewis Smith, Henry Smith, Goodhart, Pilcher, Morell Mackenzie, Conway Evans, and others.

I am criticised for not mentioning Krönlein's autopsies, in which there were cases of laryngo-tracheal diphtheria, without discoverable disease in the parts above. Finding post-mortem laryngo-tracheal diphtheria without any accompanying exudation in the throat or nose furnishes no evidence that the disease had *not* involved those parts, for the post-mortem examination does not reveal the progress of, but rather the completed disease only; and all of us know from clinical experience that, as the disease invades the larynx, it not infrequently disappears from the throat.

I quoted Krönlein no farther then, for the obvious reason that I was considering the progress of the disease, and the prevention of the same. Dr. Latham's excellent words are here highly applicable: "So far as morbid anatomy contemplates the last or latest results of disease that are fixed and irremediable, and unalterable, its value is very small. But so far as morbid anatomy contemplates *disease in progress*, and scrutinizes and explains its organic processes, its value is very great."

I suggested that early operation in croup might prevent the spread of the disease into the deeper air-passages, and this suggestion was based on the fact that, in my own cases, there has been no tendency to an extension of the disease below the tracheal wound, *when it had not done so prior to the operation*. Passavant has since made the same suggestion. Guttman has since

[5] Diseases of Children, Wm. Wood & Co., 1882, p. 136.

reported one hundred and sixty five autopsies, in which the disease did not, in any instance, leap the larynx in extending into the trachea and bronchi, but always first involved the larynx in travelling downward. I have shown that tracheotomy, by securing for the diseased larynx entire rest, is promotive of the cure of croup. Based on these facts, have we not every reason to hope that early operation will prevent the spread of the disease into the passages below the larynx?

If we weigh the reasons for and against early or late operation, everything is in favor of early operation.

"Performed early it [tracheotomy] snatches from certain death fully two-fifths of all the cases" has been termed by Dr. Rupp a "bald assertion," and yet he knows that this conclusion was based on the statistics of a great number of operators in different countries—not including America, where the general practice is to *neglect* the patient until the operation offers but a forlorn hope.

The statements made in my article *are* in accord with every careful essay on croup and tracheotomy which is based upon experience and a careful study of pathological findings, and it does not contain one statement which contradicts the teachings of one *accepted* authority; and that it is in accord with the present state of feeling on the subject is evidenced by a notice of it in the London *Medical Press and Circular* for April 29, 1885.

Everything that has been recently said on this subject in France and Germany has corroborated and verified every position which I have taken.

As to tracheotomy for croup in its imminent peril to life being one of the most dangerous operations in surgery, sufficient has been said, and it has been negatived. Dr. Rupp seems to find it a very bloody operation, for he says: "I have tracheotomized once. . . . I had been ably assisted by Dr. Stubenbord. . . . I think more than two ounces of blood were lost."

I have seen Dr. Stubenbord tracheotomize a two-year-old child that was much cyanosed, and certainly not more than half a teaspoonful of blood was lost. More than thirty physicians in this city have on as many occasions witnessed the performance of this operation by myself, and in no instance did they see their patient lose a drachm of blood. In my essay *I* said nothing about the operation being one of the "easiest things in the world," or being "simple and easy," but on the contrary I urged early operation, so as not to encounter engorged veins, etc. I said: "Operate early, very slowly, deliberately, and carefully." No greater caution could be enjoined than is found in these few words. I said: "Tracheotomy of itself, performed with care, involves little, if any danger to life;" and he who will make tracheotomy a bloody and dangerous operation is not competent to perform it. Much more skill is required in the safe administration of chloroform in advanced croup than in tracheotomizing, and if my own child were to be tracheotomized, I should be much more concerned as to who would administer chloroform than as to who should perform the operation.

Dr. Rupp's stricture on Professor Letamendi for saying, "In the days of more knowledge and less nonsense, tracheotomy will be ranked among the minor surgical operations," is a prophecy which was considered of sufficient value and importance to be at once quoted by THE MEDICAL RECORD, and has since appeared in many of the medical journals throughout the world. Dr. Rupp speaks highly of Passavant's work as a tracheotomist, and he (Passavant) says:[1] "Early tracheotomy does not belong to the dangerous operations."

The *critic* says: "We all praise Bretonneau's works on tracheotomy." Bretonneau says:[2] "We ought to hasten to perform an operation which of itself does not expose the patient to any danger."

Progress of Medical Science.

SYSTEMATIC EXAMINATION OF WET-NURSES FOR PREVENTING THE TRANSMISSION OF SYPHILIS. — Several years ago a bureau was started in Moscow (*Jahrbuch für Kinderheilkunde*), where wet-nurses could be examined by specialists with reference to old or recent syphilis. The examination was intended to be a very searching one, on account of the latency which characterizes this disease, and the possibility of future outbreaks in such cases. A certificate of immunity was withheld if suspicious glandular swellings, scars in certain places and of a certain character, suspicious pigmentations, or swellings of the bones were present, or if there was a history of repeated miscarriages. The condition of the nipples was especially noted. Of 490 women, who were examined in the course of three years, seventeen per cent. were refused certificates of immunity. In an additional four per cent. of cases the evidences of syphilis were unmistakable. It is gratifying to know that this bureau appears to have met with the approval of Russian physicians. But in our own country the establishment of such an institution is hardly practicable.

CIGAR-MAKERS' CRAMP.—Dr. Torino describes a condition of tetanic spasm and pain, occurring in a patient who for nine years had been employed in rolling cigars. In consequence of the spasm attacking the muscles of those fingers only which were used in his occupation, the complaint is likened to scriveners' palsy. Dr. Torino fully describes the malady, which in its gradual onset and general progress shows a marked resemblance to ordinary writers' cramp, with the difference of the muscles affected. In a well-marked instance, the patient was unable to go through the manipulations of cigar-making more than twice or thrice, without producing pain situated in the left wrist and the back of the left thumb, index and little fingers, while at the same time the last-named was forcibly extended by a tetanic spasm, and the thumb and index-finger so strongly separated that they could not be brought together. The spasm commenced in the thumb, then attacked the index, and then the little finger, which last sometimes escaped; the middle and ring fingers were not affected. The cause of the extension was shown to be a spasm of the extensors, and not a paralysis of the flexors; for, when the attack passed off, the latter were quite normal in their action. The right hand was not affected. In analyzing the manual movements of cigar-making, Dr. Torino finds that the left hand is used much more than the right, and that the thumb and the index-finger are the parts chiefly employed. The little finger, however, has an especial duty to perform in fashioning and pointing the end of the cigar. Dr. Torino calculates that, in making each cigar, the workman's thumb and index-finger make three distinct movements; so that, at the rate of manufacture of 300 cigars a day, during nine years of 290 working days in the year, the particular movements concerned in the production of the painful tetanus must have been performed 2,470,500 times. — *The London Medical Record*, April 15, 1885.

A NEW-BORN INFANT OF EXTRAORDINARY SIZE.—Dr. Eddowes reports the birth of a male child, weighing twenty pounds and two ounces, and measuring twenty-three inches in length, with a circumference of fourteen inches and a half around the chest. The monster was well developed and healthy.—*Lancet.*

FOR GASTRIC VERTIGO, with disturbed circulation, Professor Da Costa administered, in the case of a man:

℞. Argenti oxidi ..... gr. ss.
Ext. hyoscyami ..... gr. ij.
M. Sig.—In pill form ter die.

He also prescribed pepsin at meals.—*Col. and Clin. Record.*

Eucalyptus in the Treatment of Typhoid Fever.—Leighton Kesteven, of Brisbane, Queensland (*The Practitioner*, May, 1885), having made an extended trial of eucalyptus in the treatment of typhoid fever, both in hospital and private practice, was so pleased with the favorable results obtained that he now warmly commends the drug to the profession for further trial. Of two hundred and twenty cases of the disease which he attended in about eighteen months, there were only four deaths. He gives ten minims of the drug every four hours. "Without being absolutely nauseous, however, this medicine does not agree well with all stomachs, but this difficulty can be entirely overcome by careful emulsification, and the addition of half a drachm each of aromatic spirits of ammonia, spirits of chloroform, and glycerine, the latter entirely removing the rough semi-resinous taste of the oil. The effects of this medicine are, in brief, the following: First, it steadily and permanently reduces the force and frequency of the pulse. Indeed in one or two cases I noticed this result obtained with almost marvellous rapidity: in one case in particular, the pulse, from being a sledge-hammer pulse of 120, went to 90 within an hour of the first dose of the medicine, and never went above 90 again. Secondly, lowering of the temperature. This occurs less rapidly, and (it has occurred to me) might be entirely secondary to, and dependent on, the lowering of the pulse. Thirdly, the beneficial effect on the tongue is very marked, almost immediately alleviating the distressing dryness so universal in typhoid, and removing the thick brown coating, leaving but proportionately little fur, and frequently cleaning the tongue entirely in a very short time. Fourthly, the skin, along with the reduction in its temperature, becomes moist and soft in contrast with the harsh, dry, hot skin so frequent and persistent, conferring a corresponding increase of comfort to the sufferer, who has previously felt as if his skin had been drawn tight all over his body. This alone is a boon to the patient of no small import." Concerning diet and general treatment, the author says: "In all severe cases I order whiskey from the commencement of the case till normal temperature is attained, giving on an average five to ten ounces per diem, usually in milk and soda-water. In ordinary cases I feed the patient on milk thickened with isinglass, beaten-up eggs, milk and soda, cocoa, and —where diarrhœa exists—ground rice and milk. In asthenic cases chicken-broth (concentrated to ten ounces of clear broth from a whole fowl) given in ounce doses to avoid filling the stomach with too large a quantity of fluid for weak digestion, the juice of half-cooked mutton, or beef tea made in a pot without water and strained through fine muslin. For the abdominal tenderness frequently-changed ice-cold compresses, and ice to suck; ice to the shaved head for cephalalgia; and frequent cold packs from the head to the knees at any rise of temperature. All the linen is changed morning and evening, without ever altering the patient from the horizontal position. All nourishment is given in small quantities at short intervals, thus receiving better digestion than when given in larger quantities at longer intervals."

Aneurism of Splenic Artery Rupturing into Stomach.—At a recent meeting of the London Pathological Society, Dr. S. West showed an interesting specimen, illustrating the above accident (*Lancet*, March 21, 1885). It was taken from a male subject, aged fifty-six, who had suffered from hæmatemesis and was given to drink. He had had a similar attack of hæmatemesis fourteen years previously. He suffered from great pain and flatulence with looseness of the bowels. When he was admitted on January 18, 1885, he was weak and faint, and passed much blood in the motions, which were long afterward of a tarry aspect. The patient was anæmic; there was slight enlargement of the liver and some tenderness of abdomen. On January 28th a pint of bright blood was vomited, and in half an hour the patient died. The stomach was found at the autopsy to be full of blood; there was an ulcer one inch in length, and situated midway between the œsophagus and pylorus. An aneurism of one of the chief branches of the splenic artery was found to be adherent to the stomach on the one hand, and on the other to the pancreas; there was much chronic inflammatory tissue around the aneurism. A prominence projected through the base of the ulcer in the stomach. There were two slight losses of substance at other parts of the stomach, which were of old date. The liver and kidneys were cirrhotic; the pleuræ were adherent.

The Treatment of Sclerosis of the Coronary Arteries.—Leyden has published in the *Centralblatt für die Ges. Therapie* the plan of treatment which he adopts in cases of sclerosis of the coronary arteries. He recommends first of all some hygienic precautions, such as moderate diet and exercise, and the avoidance of hard work and violent emotions. Some weeks may be spent very profitably every year at Carlsbad, Marienbad, or Kissingen. When the symptoms of angina pectoris have appeared, the treatment must be directed chiefly against them. During the paroxysm complete rest is essential, and means must be taken to prevent paralysis of the heart; hot drinks, champagne, camphor, ether, musk, valerian, etc., are all useful, while digitalis and bromide of potassium are dangerous. The former, however, is to be given where there is œdema of the lungs, and when the arterial tension is much diminished. Narcotics must generally be avoided, but an exception can be made in favor of morphia, which is useful when there is much dyspnœa. Inhalations of chloroform and ether are not exempt from danger. Inhalations of nitrite of amyl give excellent results, but only when the vessels are contracted. As for the nitrite of sodium, Leyden has not seen any benefit from its use. When the quantity of urine is diminished, saline diuretics, scilla, and caffeine are indicated. Warm baths often do more harm than good, but a poultice on the chest is generally agreeable to the patient.

The Treatment of Pleuritis in Children.—Biedert believes that in a given case of this disease, when crepitation of the opposed pleural surfaces announces that exudation has begun, an attempt should be made to shorten the disease, if this be possible. One measure which is suggested, with this end in view, is the immobilization of the diseased side of the chest by the firm application of strips of plaster. Ice-bags are approved to reduce temperature and benumb pain. Quinine and salicylate of soda are also approved in the febrile stage, and digitalis if the fever is accompanied by a weak and rapid pulse. Resorption of the exudate is the rule, and this action may be assisted by the use of proper vesicants and irritants to the skin, cold water applications, and digitalis. If absorption does not begin within a few days, an exploratory puncture should be made with a fine disinfected needle. If the pleural cavity is found to contain serum, it should be withdrawn by aspiration, a fine trocar being used. Should the disease process extend through three or four weeks, the exudate will probably become purulent, and demand an operation for its removal. This operation should be aseptic, the incision should be made in the posterior axillary line, and along the upper border of the eighth or ninth rib. If resection is required, the incision must be made along the middle of the rib. The main object is the securing of good drainage, and having introduced the tube in the most dependent position possible, it is advised that it be made sufficiently long to have its extremity rest in a basin by the side of the bed, containing a four per cent. solution of boric acid. The wound should be covered with strips of collodion gauze. Drainage will usually cease after three weeks. The dressings should be changed every day at first, but after a few days the intervals can be longer. Washing out the pleural cavity is not recommended, and in most cases is thought to be ill-advised. If the drainage is what it ought to be, no washing out will be necessary.—*Archives of Pediatrics*, April 15, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 30, 1885.

THE MEDICAL CHARITY PROBLEM.

WITH feelings of some interest, we have recently examined the last annual reports of our leading dispensaries and hospital out-patient departments, to see what progress, if any, has been made in the work of discriminating between worthy and unworthy applicants for aid. The result of our examination is, on the whole, disappointing. The usual allusions are made to the "deserving poor," and it is stated that "careful efforts" have been made to withhold charity from all those able to pay, or from any cause unworthy; but the record of specific effort in this direction is most meagre. The most decisive step has been taken by the managers of the German Dispensary. From its report we learn that a special committee was appointed "to consider what ways and means could be devised to stop the abuse of our institution by patients who are able to pay." During the month of December last, the circumstances of every new applicant were inquired into with special reference to this fact, and we note with interest the committee's findings. "Eight per cent. of all applicants had to be dismissed as being fully able to pay, and the cases of seven per cent. were doubtful;" and it has been decided that during the present year, all applicants shall be submitted to a liberal examination in regard to their ability to pay for the service they ask.

Referring to the whole number of patients treated in this institution, we find that eight per cent. represents nearly twenty-five hundred persons. It is not erroneous to regard these figures as applicable to any other similar institution. It is not possible to form any accurate estimate of what percentage of the whole population seek dispensary treatment. It varies in the reports from eight in some cases, to sixteen in others. We are inclined to regard the latter figure as expressing more nearly the truth, and, judged by the figures of the reports, it is indeed too low. Our city and floating population (which latter class often seek aid) numbers at least one million three hundred thousand. During the year 1884 eight institutions alone (exclusive of two of the largest, from which reports have not been received) treated about one hundred and fifty thousand patients. If we could gather the facts and figures concerning all the smaller, private, and church institutions, the total number of persons aided would probably amount to a quarter of a million. The paying population then is reduced to about ten hundred and fifty thousand.

What is the supply of physicians to minister to this number of people? The edition of "Wilson's Business Directory" for 1885, gives as the number of persons in New York City, legally qualified to practise medicine, about twenty-two hundred and fifty, or one to about every four hundred and sixty inhabitants. The foregoing figures give some idea of the extent of our charity to those whom we may consider our "walking cases." This is exclusive of those treated at their homes by dispensary physicians, and those in the beds of our large hospital wards.

The conclusions from these facts are not altogether assuring. Indeed they are quite disagreeable; but unpleasant revelations ought not to divert us from our search after the bottom truth. From the foundation of the world, true charity has always suffered from sentimentalism, and the effect thereof has been unfavorable upon both the bestower and the recipient. Says Spencer: "Self-sacrifice passing a certain limit, entails evil upon evil: evil upon those for whom sacrifice is made as well as upon those who make it. . . . The continual acceptance of benefits at the expense of another is morally injurious. Just as much as unselfishness is cultivated by one, selfishness is cultivated by the other." We hardly suppose that our dispensary managers would regard the above language as applicable to themselves. "All this is said of altruism," they would say, "but we are not altruists." Perhaps not in name, but a very casual glance at any one of our institutions will carry conviction that scores of people are being treated free who could pay moderate fees. In some institutions a small charge is made for medicine; in others, tickets are issued entitling the holder, on payment of a small sum, to attendance for a specified time. Both of these plans (though the latter is not free from objection) are good as far as they go, but the trouble is, that they do not go far enough. We have enough and more than enough dispensaries in New York. Our colleges, also, will always attract clinical material. A valuable suggestion made some time ago by a contributor to THE RECORD, was, that the clinical material in the various dispensaries should be rendered available (so far as was necessary) for the colleges. Impracticable as this may seem, we may yet be forced to do it.

Our charitable work must be more systematic. The circumstances of patients must be more clearly inquired into. The longer we defer this work the more surely are we sowing the wind and becoming liable to reap the whirlwind, and the more difficult will be the inauguration of that reform which is demanded both by justice to the profession and by the best interests of the community. At present we are shirking the task.

"A NEW DISCOURSE ON A STALE SUBJECT."

IT may be that the truly epochal events in the world's history take place quietly, unnoticed by contemporaries, and only brought to their merited prominence by the discerning hand of later historians. We believe that there is before us an illustration of this. In the domestic history of man we see at one end two forked sticks supporting a pole; at the other the porcelain basin, traps, toilet paper, and all the other Sybaritic appliances of a modern closet. Standing half-way between is the herete

fore unknown figure of Sir John Harington, who, in 1596, gave the world the earliest description of a water-closet, in a small pamphlet entitled "A New Discourse upon a Stale Subject." We are indebted to our ever-enterprising contemporary, *The Sanitary Engineer*, for a republication of the important document. Sir John wrote in a rude age, but the sensibilities of the people had not then been materialized and deadened by modern science, which now discusses with equal freedom the arrangements of a water-closet and the adulterations in candy. Sir John, therefore, introduces his subject in a periphrastic and half-apologetic manner.

He remarks: "For when I have found, not only in my own poor confused cottage, but even in the goodliest and stateliest palaces of this realm, notwithstanding all our provisions of vaults, of sluices, of grates, of pains of poor folks in sweeping and scouring, yet still this same whoreson, saucy stink, though he were commanded on pain of death not to come within the gates, yet would spite of our noses, even when we would gladliest have spared his company, prease to the fair ladies chambers; I began to conceive such a malice against all the race of him, that I vowed to be at deadly feud with them, till I had brought some of the chiefest of them to utter confusion; and conferring some principles of philosophy I had read, and some conveyances of architecture I had seen, with some devices of others I had heard, and some practices of mine own I had paid for, I found out at last this way that is after-described, and a marvellous easy and cheap way it is; and I dare speak it upon my credit, not without good experience, that though it be neither far-fetched nor dear-bought, yet it is good for ladies."

Having thus given a brief review of reasons and effects, Sir John describes in a vivid and realistic style the state of the closets of that period, and the methods which had so far been employed to avoid the malodorous results of defective sewage. It is interesting to note that our author is moved entirely by æsthetic feelings to gain the object which he seeks. There is no word regarding disease, but only of stenches and their unpleasantness. After many trials Sir John devised a water-closet, very much in principle like the modern ones. A tank of water above, a pan, a stop-cock, etc., are among the features of his invention, which is illustrated with some mediæval cuts. Whether his device became widely adopted historians do not say. These learned gentlemen tell us much of kings and battles, and but very little of the things that really occupied the thoughts and time of the people. But at any rate, we have Sir John Harington's invention at the present perfected and adopted to an extent no doubt far beyond the dreams of the philosophical student of the "Stale Subject." And certainly some credit should be given to a man who was the first apostle of sweetness, if not of light.

VIDERE QUAM ESSE.

Dr. J. B. Murdoch, of Pittsburg, Pa., has been calling the author of "The Physician Himself" to account for the unsound ethics which crops out in some places in his work. The spirit of its teachings, says Dr. Murdoch, is to give too great prominence to appearances. The *suaviter in modo* is everything. The following extraordinary passage from the book is quoted:

"Take care to be neat in your personal appearance; above all else wear a clean shirt and clean collar; for if you dress well people will employ you more readily, accord you more confidence, expect a larger bill, and pay you more willingly. You never heard of a bank swindler, or a confidence man, or a gambler, or a counterfeiter, or pseudo-gentleman of any kind, who dressed shabbily or appeared coarse. Such people are all students of human nature, and no matter how abandoned they are, no matter how tarnished their characters, or how blackened their hearts, they manage to hide their deformities as with a veil, from all but the few who know their true characters, by assuming the dress and manners of gentlemen."

Appreciating the curious logic of the above, the author tries to turn it by saying that if genteel dress does so much for a bad man, how much more will it do for a truly good one, like the physician.

Another curious passage is the following:

"Do not lend yourself too freely to other physicians and surgeons; never make a habit of playing second fiddle by giving chloroform, etc., in surgical cases. If you go and do some secondary part in a surgical case you will be looked upon as a lesser light to the one you assist; and you will take a position of neither honor nor profit, and will reap nothing but responsibility."

We call attention to these points because it has happened that Dr. Cathell's book has been widely circulated and almost uniformly endorsed. A little thought will convince any one that its teachings are not perfectly safe, and that the principle *videre quam esse* pervades it to an unpleasant and dangerous extent.

AN EDITORIAL JUBILEE.

The first number of the hundredth volume of *Virchow's Archives* has been issued. "It was a jubilee day," says Professor Ewald, "not only for Virchow and his associates, but for the whole medical world."

Professor Virchow takes the occasion to call attention to the history and growth of his journal, and he shows that his success as an editor is esteemed not the least among the many triumphs of his life. The *Archives*, writes Virchow, are now read in every civilized land. The articles which they contain are everywhere quoted and reproduced. The series of one hundred volumes embraces contributions which have had an influence of unexampled importance in determining the progress of medical science, and, in writing the history of medicine, their pages must be continually consulted.

Virchow started his *Archives* thirty-eight years ago, being assisted at the time by a number of friends, of whom all, we believe, are now dead. The new journal soon established itself as a periodical of remarkable scientific merits. Its articles were always carefully prepared, and generally contained the results of fruitful, original research in physiology, pathology, or medicine. The editor impressed upon it the stamp of his own vigorous personality. To publish an article in Virchow's *Archives* became somewhat of a distinction.

In one thing, at least, Virchow's journal is unique. Although purely scientific in character, containing only weighty original articles, it has obtained a very large

circulation, perhaps as great as that of any medical journal in Germany. At the present day it does not perhaps hold quite so prominent a position as the organ of the best medical thought of Germany as formerly, but it still maintains, in every way, its high standard, and we trust that it will continue to do so.

THE VALUE OF STATISTICS ONCE MORE.

At the recent meeting of the French Ophthalmological Society, held in January of the present year, M. Vacher, of Orleans, read a paper on "Astigmatism and Cataract," in which he concluded, from a study of upward of fifty cases, that astigmatism was a predisposing cause of cataract. He thought it very probable that the crystalline sclerosis was due to the excessive action of the ciliary muscle occasioned by efforts to correct the astigmatism. In the discussion which followed, M. Martin, of Bordeaux, said that he had for a long time examined every case coming under his observation, with the special view of determining this relationship. His conclusions were, however, not exactly in accord with those of M. Vacher, for he had found that astigmatism hindered the development of cataract. Which is correct? Perhaps the two conditions bear no relationship to each other. Who knows?

AUSCULTATORY-PERCUSSION AND AMERICAN PRIORITY.

We are accustomed to think, in these days of many medical journals and rapid mail communication, that whatever of value is advanced by workers in any part of the world cannot long escape the notice of all the rest, in whatever part of the footstool their lot may be cast. That this is true, as far as the readers of The Medical Record are concerned, we venture to affirm with all becoming modesty. But we are occasionally grieved to see that our brethren across the water are not always as well informed as it is the privilege of our readers to be.

In a recent number of the *Rivista Clinica* Dr. Aurelio Bianchi has published an excellent article on "The Stethoscopic Auscultation of Percussion," in which he describes the method very clearly and defines its application. The author says that he was led to study the subject from some American and German publications, which hinted at the possibility of some such method of physical investigation, but which contained nothing of practical applicability. In a later number of the same review Dr. C. Bonfigli takes the writer to task for claiming originality in a method that was not new. Dr. Bonfigli asserts that he had mentioned the combined method in a note to a translation of Guttmann's treatise in 1873. He very modestly disclaims any desire of having the procedure called Bonfigli's method, but he protests against giving it the name of Bianchi.

To us on this side of the water, it would seem more proper, if any name other than the excellent one of auscultatory-percussion be desired, to call it Cammann's method; for certainly the late Dr. G. P. Cammann's title to priority can hardly be disputed, since he published a description of the procedure, as elaborated by himself and Dr. Alonzo Clark, in *The New York Quarterly Journal of Medicine and Surgery* for July, 1840. This article was at the time extensively noticed in both American and European journals, a particularly good abstract appearing in the *Archives Générales de Médecine* for February, 1841. Dr. McBride, of this city, also published a paper some five or six years ago on auscultatory-percussion, and described a new solid binaural stethoscope for convenient use in the combined method.

Dr. Bianchi is one of the most prominent upholders of Pacini's claims to priority in the discovery of the comma-bacillus, and has just published some previously unedited notes of Pacini in substantiation of these claims. And we are therefore convinced that, did he know of the articles above referred to, he would be the last one to withhold the credit due to American physicians for discovering this valuable method of physical examination, which he himself has done so much to popularize in his own country.

THE REST TREATMENT FOR MASTITIS.

Most physicians of experience have learnt that in a threatening inflammation of the mammary gland, rest is the best single therapeutic agent which can be employed. The older methods, still advised, unfortunately, by some doctors and by many nurses and old women, of rubbing down the swelling, applying various liniments, and of persistently trying to empty the breast, can be very readily shown to be harmful and irrational.

Dr. Philander A. Harris has recently drawn attention to this subject (*American Journal of Obstetrics*) by a forcible advocacy of bandaging and rest in the treatment and prevention of mastitis. The bandaging is done so that it involves not only some support to the breast, but produces a slight compression, while the "rest" means rest from friction by nurses and from suckling by the child. In bandaging, Dr. Harris uses cotton batting and roller bandages, which latter he believes preferable to adhesive plaster. By the treatment which he advocates, he has succeeded in preventing the supervention of abscesses in all of the fifteen cases in which it was applied. It appears evident, however, that in some of these cases no abscess would have occurred in any event under ordinary care. In other cases the fact that no abscess occurred after the development of the symptoms recorded is little less than marvellous.

There is no doubt that rest of the gland and proper bandaging are proved to be the best measures for preventing and treating mammary abscess. They will not always succeed, however, for in some cases there is a constitutional vice that no roller bandage can touch. On the other hand, mild and careful friction to the surface of an irritated and painful gland are sometimes grateful and harmless. Beware only, we say, of trusting to drugs which are affirmed to check or hasten secretion or to soften the breast, for the existence of such has no scientific demonstration.

Dr. Harris makes another point worthy of being more fully examined, viz., that in obstinately sore and painful nipples, the best treatment is to bandage up the gland and rest it until the nipple is well. Then apply the child to the breast again and the milk will return.

The conclusions of the author referred to are as follows:

"1. That the breasts soon after delivery are strongly disposed to secrete milk, and will usually continue to

do so for a few days, even if they be not nursed. If no attempt be then made to nurse or withdraw the milk, the secretion rapidly diminishes and they return to their normal size and condition of inactivity.

"2. That, as a rule (to which there are probably few if any exceptions), the retained secretion does not undergo changes which convert it into an irritant fluid, but instead it remains innocuous to the walls of the ducts and acini which contain it, and under favorable conditions is finally absorbed without trouble or embarrassment to either the normal or inflamed adjacent tissues.

"3. That, as a rule, the secretion of milk continues only while the natural stimulus, as nursing or other means of emptying the breast, continue to be employed. That the secretion, either in the normal or inflammatory condition, begins to abate when such stimulus is withdrawn, and will entirely cease after a week or two.

"4. That an abundant secretion of milk which has recently and entirely ceased as the result of a complete withdrawal of stimulus, may be again recalled upon the reapplication of the child.

"5. That the presence of a decided inflammatory movement in the breast greatly diminishes secretion in the gland.

"6. That the sympathetic relation between the two breasts is almost, if not wholly, a sensory one. That neither the function of secretion nor the condition of the circulation in one breast is appreciably and directly affected by either physiological or pathological processes which may be going on in the other."

We would add that the pain and agony which are so vividly depicted by some writers as the inevitable consequence of mastitis are not always in reality excessive, the suffering being often as much mental as physical.

News of the Week.

Dr. E. Darwin Hudson's Article on "Limitations of the Diagnosis of Malaria," read at the recent meeting of the Section on Practice of Medicine, of the New York Academy of Medicine, has been unavoidably crowded out of the present issue, but will appear in our next.

The American Climatological Association held its second annual meeting at the Academy of Medicine, in this city, on May 27th and 28th. The following papers were read: Address by the President of the Association, A. L. Loomis, M.D., of New York; "The Climate of Mexico," by H. D. Didama, M.D., of Syracuse, N. Y.; "Antiseptic Inhalations," by Beverley Robinson, M.D., New York; "Catarrhal Affections of the Nasal Cavities as a Cause of Pulmonary Phthisis," by W. C. Jarvis, M.D., of New York; "The Home Treatment of Consumption," by F. C. Shattuck, M.D., of Boston, Mass.; "Further Consideration of Pneumatic Differentiation, with Demonstration of the Pneumatic Cabinet," by H. F. Williams, M.D., of Brooklyn, N. Y.; "A Rule for the Even Division of Climate, based upon the Average of the Combined Atmospheric Humidities in the United States," by C. Dennison, M.D., of Denver, Col.; "Elements of Climate and their Relations to Pulmonary Consumption," by J. H. Tyndale, M.D., of New York; "Geographical Distribution of Phthisis in Michigan, with Sketch of Topography," by E. L. Shurley, M.D., of Detroit, Mich.; "The Treatment of Laryngeal Tuberculosis," by E. F. Ingalls, M.D., of Chicago, Ill.; "The Problem of Acclimatization," by J. H. Platt, M.D., of Brooklyn, N.Y.; "Tampa Bay as a Health Resort," by J. C. Wilson, M.D., of Philadelphia, Pa.; "The Results of the Home Treatment of Consumption Contrasted with those of Changed Residence and Climate," by E. D. Hudson, Jr., M.D., of New York; "Hay Fever and Allied Affections," by F. H. Bosworth, M.D., of New York; "The History of the Stethoscope, with the Presentation of a Modification of the Cammann Stethoscope," by D. M. Cammann, M.D., of New York.

An Episode in the Hoyt Will Case.—Dr. Millard testified that Miss Hoyt had many imaginary ailments, among them a belief that she had diphtheria and that she had coagulated blood upon her brain. The doctor testified that to humor her he called a professional cupper and leecher, a man named Hansen, who conducted an employment agency for nurses. This man bled her a trifle behind the ear and then showed her a clot of blood on a plate, and she after that considered her head all right. "Did the nurse obtain the blood from her head?" General Butler asked. "He wasn't a nurse," answered the witness; "he only kept a nurse agency." "If he kept a nurse agency," returned the Massachusetts statesman doggedly, "he was a nurse." "Then I suppose if a man keeps a stable he's a horse," suggested Senator Evarts wearily. "Or if he drives an ice-wagon he's a cold in the head," murmured Mr. Root sadly.

Typhus Fever.—Several cases of typhus fever have appeared in the city since the 4th inst.

Bills Passed by the New York Legislature.—A bill establishing a hospital for the treatment of wounded, north of One Hundredth Street. Exempting from taxation the property of Mount Sinai Hospital, and of the Montefiore Home for Chronic Invalids, and of increasing the salaries of police surgeons. Incorporating the New York College of Medicine and Surgery. Amending and incorporating the Long Island College Hospital. For the better protection of public health and drainage of land. Appointing twenty additional sanitary inspectors.

Regulating Dental Practice.—The Legislature of Wisconsin has passed an act creating a State Dental Board, the intent of which is to prevent incompetent persons from practising dentistry, and among others the Governor has appointed Dr. Edgar Palmer, of La Crosse, son of Walter Palmer, of this village, to be one of the Board.

The Congress of the Italian Medical Association is to be held at Perugia in September.

The French Association of the Advancement of Science meets at Grenoble, beginning August 13, 1885.

The New Surgeon-General with the Government of India.—Surgeon-General Benjamin Simpson, M.D., has succeeded Dr. J. M. Cuningham as Surgeon-General and Sanitary Commissioner with the Government of India. Dr. Simpson entered the Bengal Medical Service in the year 1854.

THE WAVE OF CHOLERA IN CALCUTTA.—Since the year 1881, cholera in Calcutta has shown a tendency to increase to the rate which obtained some years before the introduction of filtered water. Mr. Cotton, the municipal member of the late Government Commission, has carefully analyzed the cholera statistics of Calcutta as compared with those of the surrounding districts, and he thus traces the increase in cholera to a general epidemic wave passing over the neighboring districts as well as Calcutta itself.—*Indian Medical Gazette.*

VACCINATION WITH FEVER VIRUS.—The following telegram comes from the city of Mexico: "The Government of Mexico has permitted the garrison of Vera Cruz to be vaccinated with yellow-fever virus, according to Dr. Carmona's system. Experiments were first made on prisoners who volunteered for the purpose. Persons vaccinated with the virus have all the premonitory symptoms of the fever. It is thought that the inoculation will serve as a complete protection for four or five years. Great interest is felt in the discovery, and the system will be tried on the west coast and in Sonora."

DISFRANCHISING DISPENSARY PATIENTS.—The English Government has passed a law disfranchising all English voters who have accepted medical relief from the parish. This, throughout England, will bar probably two hundred thousand, or one-tenth of the whole number of voters.

CHOLERA IN FRANCE.—A few cases of genuine cholera are reported in Marseilles.

A NEW UP-TOWN HOSPITAL IN NEW YORK.—The corner-stone of the Manhattan Hospital, at One Hundred and Thirty-first Street and Tenth Avenue, was laid last week. The hospital is being built by the Manhattan Dispensary Association.

DR. HERBERT E. SMITH, of New Haven, has been appointed Professor Silliman's successor in the Chair of Chemistry in the medical department.

THE INTERNATIONAL SANITARY CONFERENCE, which met at Rome during the past week, is reported to have declared against the utility of land quarantine.

OFFICERS OF THE INTERNATIONAL MEDICAL CONGRESS.—A full list of the officers of the prospective Medical Congress, as arranged by the executive committee, has been published in the *British Medical Journal* and other foreign journals.

DISTINGUISHED HONOR CONFERRED ON A NEW YORK SURGEON.—The King of Greece has recently conferred on Dr. Morris H. Henry, of New York, the Gold Cross, and created him an officer of the Royal Order of the Saviour. The honor was conferred for services rendered to medical science, on the recommendation of the Faculty of the University of Athens.

CIVIL SERVICE AND THE HEALTH DEPARTMENT.—For the information of applicants for employment in the Health Department, the operation of the existing Civil Service laws, as they affect appointments by the Board of Health, are thus explained: Every applicant must be examined and recommended by the Civil Service Examiners before his application can be considered by the Health Commissioners, and for every vacancy to be filled by them the Civil Service Commission must submit three names. Thus the power and discretion of the Board of Health begins and ends with the selection of one of these three candidates nominated to fill any one existing vacancy. Pursuant to a recent requisition of the Board of Health, the Civil Service Commission will submit, on or before June 1st, prox., a list of qualified candidates, from which the Health Commissioners may appoint fifty assistant sanitary inspectors for the summer service of this department, the service being of two months' duration, and the pay one hundred dollars per month. Candidates for such service may at any time present themselves for the Civil Service examination, which is, as already explained, the indispensable preliminary to consideration of their qualifications, personal and other, by the Health Board.

THE NEW YORK NEUROLOGICAL SOCIETY.—At the last meeting of this Society the following officers were elected for the ensuing year: W. R. Birdsall, M.D., President; L. Weber, M.D., First Vice-President; C. L. Dana, M.D., Second Vice-President; G. W. Jacoby, M.D., Recording Secretary; W. M. Leszynsky, M.D., Corresponding Secretary; E. C. Harwood, M.D., Treasurer; E. C. Seguin, M.D., T. A. McBride, M.D., E. C. Wendt, M.D., A. D. Rockwell, M.D., B. Sachs, M.D., Councillors.

AN IMPOSTOR.—The profession is warned against an impostor who has been "doing" the city for some months past. He claims to be a graduate of the New York College of Physicians and Surgeons, 1877. His plan is to tell a piteous story of a lost pocket-book, and borrow as much as he can on the strength of it. Result to the compassionate lender—as usual. He is almost a mulatto in appearance, and gives various addresses. This warning is given to possible future victims.

THE MEDICAL SOCIETY OF NEW JERSEY will hold its next annual meeting at Long Branch, June 9th and 10th. The Oregon Medical Society meets on same dates at Portland, Or. The Ohio Medical Society meets at Dayton, O., on June 4th and 5th.

Reviews and Notices.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1884. Vol. I. Edited by AUSTIN FLINT, JR., M.D. Pp. 615. New York: D. Appleton & Co. 1885.

THE Association is certainly to be congratulated on the appearance of this, their first official publication. To the future student of the medical history of the Empire State, it will furnish probably the most complete *résumé* of the events leading to the formation of the new organization that has yet been published. The position of the Association on the ethics question is of course too well known to call for special comment. The papers published are all meritorious, and cover a wide range of topics of practical interest to the profession. The one by Dr. Lynde on "The Function of the Auricles" introduces several new ideas on cardiac physiology. He maintains that the auricles are but the expanded terminations of the veins, and do not contract. The paper called forth an interesting discussion. The compactness of the volume, with the high scholarship of its contents, combine to make it a valuable addition to medical literature.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Thirty-sixth Annual Session, held at Scranton, Pa., May 27, 28, and 29, 1885.

(By Telegraph to THE MEDICAL RECORD.)

FIRST DAY—WEDNESDAY, MAY 27TH.

THE meeting was called to order by the President, DR. EZRA PALLEN, of Bradford County.

REV. R. C. MULLER made the prayer.

PRESIDING JUDGE HAND made an address of welcome, referring to the important relations of the legal and medical professions.

A telegram was received that the Legislature had passed the bill creating

A STATE BOARD OF HEALTH.

It is hoped it will be signed and become a law before the Society adjourns. The crying need of State sanitation is shown by the Plymouth epidemic, which has only been combated by individual benevolence and devoted physicians.

DR. H. H. SMITH offered a resolution, which was adopted,

FORFEITING THE CONNECTION OF A COUNTY SOCIETY WITH THE STATE SOCIETY

when the former seeks general legislation without consent of the State organization. This will probably be a damper on the bill pushed by the Philadelphia Society to create a licensing board, which implied a step toward the divorce of the licensing and teaching powers.

DR. S. S. SCHULTZ, Superintendent of the State Hospital for Insane, Danville, read

A PAPER ON MENTAL DISORDERS.

Insanity is only an index of brain-lesions, the name is analogous to the terms dyspepsia, dropsy, etc., meaning not an entity, but a symptom or group of symptoms produced by structural lesions in the organ concerned. Apoplexy, acute meningitis, etc., produce structural changes without necessarily causing insanity, while the congestion of typhus, etc., produce it at least temporarily. There is no sharper line between sanity and insanity than between health and disease generally. Probably no causes can produce insanity without some original peculiarity of nerve-structure. This predisposition, hereditary or acquired, explodes into insanity when some severe stress is laid upon the patient. Insanity may exist for years unrecognized, even by the patient's intimates. In such case, if fortune smiles, the patient may live and die a real but unrecognized lunatic, while a business reverse or great disappointment may demonstrate his insanity and recall many previously unnoted evidences of the disease. This is analogous to other histories, as that of atheroma.

In the treatment of insanity the vital point is the removal of the cause, if possible. This cannot be done at home. The religious monomaniac requires his emotional side to be rested and his reasoning powers called into action. Though a brain-lesion producing insanity may heal, it will leave a structural change analogous to pleurisy, etc., and chronic insanity may remain.

DR. J. G. RICHARDSON, of Philadelphia, read

AN ADDRESS ON HYGIENE

and State Medicine. The doctor looked hopefully upon the ability of sanitary science to vastly reduce mortality from future epidemics. He referred to the claim of English sanitarians that more lives had been saved in their army in ten years by better observance of sanitary laws than were lost at Waterloo. He spoke of the value of meteorological observations, as inaugurated and illustrated by the Government service in this country, where the conditions are so favorable for gathering valuable data from an immense area. The data so obtained should be practically utilized, as in determining what time convalescents and children shall be moved or taken out of doors, etc.

THE TEACHING OF SANITARY SCIENCE IN THE SCHOOLS

is important. The law of the survival of the fittest should become the foundation of a wide scheme of sanitary and hygienic improvement. While deploring agnosticism, the doctor thought its spread would induce better appreciation of sanitary laws, by the additional importance which the things of this world obtain by the extinction of the hope of a better.

The address in

OTOLOGY

was given by DR. CHAS. S. TURNBULL, of Philadelphia, with particular reference to the treatment of the ear in children. He said that ophthalmology is exalted while otology is too much neglected.

EARS ARE DAMAGED BY INDISCRIMINATE DRENCHING AND SWABBING;

soapy solutions irritate, milk ferments, and with cotton, causes inflammation.

THE MAJORITY OF CASES OF OTORRHŒA IN CHILDREN UNDER TWO YEARS WOULD RECOVER WITHOUT DAMAGE TO HEARING IF LET ALONE.

The doctor characterized the sponge with handle, sold by druggists under the name of "aurilave," as a dangerous implement. Impacted cerumen should be first soaked by warm alkaline solution, then syringed with warm water. Serum, mucus, or muco-pus should be wiped out with absorbent cotton. If the discharge be fetid, boracic acid in solution, or suspension, or as an insufflated powder is best. The most essential point is freeing the middle ear from secretion. This should be done in adults by Valsalva's experiment or Politzer's method; in children, by forcible inflation by the essayist's method, as follows: one nozzle of an auscultation tube, protected by a perforated lead-pencil rubber cap, is held in the patient's nostril, the other nostril closed, and as the child cries or blows out the surgeon blows a short blast through the tube, which inflates both ears.

After eczema, chronic otorrhœa, and removal of wax keep the canal greased. A peculiar deafness in old people, caused by atrophy of the ceruminous glands, itching, scratching with hair-pins, etc., until the membrana tympani is badly relaxed, can be relieved by frequent applications of an ointment of morphia, yellow oxide of mercury, and cosmoline to the meatus, with a strong alkaline gargle for the throat, with perhaps use of artificial teeth. In plastic inflammation of middle ear, chronic deafness, and tinnitus aurium, treatment remains unsatisfactory. For treating tinnitus aurium erythroxylon coca is recommended for its anæsthetic effect on throat and Eustachian tube. He uses Squibb's hydrobromic acid and bromide of sodium in the auditory nerve disease, from the noise of machinery, etc. Where one hears distinctly only in a noise, treatment is unavailing; the patient can only leave the noise and seek outdoor employment. For wax, soak and syringe; for children's earache, hot foot-bath and aconite; for pain in ears, use dry heat and anodynes. Submaxillary ticking calls for throat treatment.

DR. EDWARD JACKSON, chief of eye clinic, Philadelphia Polyclinic, read a paper on

DIAGNOSIS OF INCIPIENT CATARACT.

He said cataract is dreaded because credited with the effects of other diseases. This implies faulty diagnosis. Subjective symptoms are negative. The ophthalmoscopic mirror eliminates error; its use requires little experience, and any perforated mirror will answer. Recognition of lens opacity only begins the diagnosis, the

share of cataract in causing symptoms must be determined. Eyes presenting cataract are apt to have more serious lesions. It is of practical importance to ascribe to cataract the things that belong to it, and to glaucoma, nerve-atrophy, choroiditis, or ametropia, the things that belong to them.

Dr. F. D. Castle, of Philadelphia, read a paper on

SOME POINTS IN OPHTHALMOLOGY.

First, how to determine whether a case of blindness is due to cataract or not if the appearance of the pupil is such as to warrant the belief that the lens is opaque; second, the probable diagnosis of cases of eye-strain in which the symptoms may be relieved by the adaptation of suitable glasses; third, the necessity of an early recognition of acute glaucoma, and the avoidance of atropia in the treatment of such cases. It is now becoming recognized that iridectomy cures only inflammatory glaucoma in which there are inflammatory symptoms in the anterior portion of the globe. This is cured by iridectomy and cannot be mistaken for cataract, while simple glaucoma is rarely benefited by operation, and requires the ophthalmoscope to diagnose from cataract. Aged pupils are grayish, from senile changes in the lens and, perhaps, atrophic changes in the choroid, reflecting more light from the fundus, suggesting cataract, while the lens may be transparent. Therefore, disregard diffuse opacity in the pupil when focal illumination is used, and do not mistake a grayish shimmer for a defined opacity contrasting strongly with its background. Diagnosis is still more difficult where there is some opacity and yet the principal disease is in the nerve and retina. Here the visibility of the posterior capsular image of a reflected candle-flame is of great diagnostic importance, as is also the amount of perception of light.

EYE-STRAIN

is exceedingly common, and in the child and young adult generally recognized at a glance, but care is needed with the aged, as incipient cataract, etc., may be present. Symptoms: Slight redness, weariness, headache, blurred vision on reading, scrofulous ophthalmia. Marginal blepharitis and *phlyctenular* conjunctivitis are often caused by eye-strain, all curable only by suitable glasses. Early diagnosis of acute glaucoma is important to avoid atropia and other mydriatics, as Loquacurs says: "Whatever dilates the pupil may cause this disease."

The society was banqueted on Wednesday evening by the Lackawanna County Society.

(We are under great obligations to Permanent Secretary Dr. W. B. Atkinson for reportorial facilities.)

(To be continued.)

THE FOURTEENTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, April 8, 9, 10, *and* 11, 1885.

Professor v. Langenbeck, President, in the Chair.

(Special Report for The Medical Record.)

The first session was called to order shortly before one o'clock in the large hall of the Royal University, which was crowded almost to overflowing by the number of delegates in attendance.

THE OPENING ADDRESS

was delivered by the President, who welcomed the members in the usual terms. He announced that, in accordance with the resolution taken at the last meeting to admit a limited number of

HONORARY MEMBERS,

the Council had nominated Sirs James Paget and Joseph Lister. The nomination was received with much enthusiasm, and the candidates were elected by acclamation.

THE ELECTION OF OFFICERS

was then held, with the following result: Vice-President —Herr Volkmann; Secretaries—Herren Gurlt and Schönborn. As the President positively declined a re-election by reason of ill-health, it was voted to postpone the nomination of his successor until the last session, Herr v. Langenbeck consenting to preside until the end of the present congress.

Herr Volkmann, of Halle, began the scientific work of the session with a most interesting and elaborate paper, entitled

SURGICAL EXPERIENCES IN TUBERCULOSIS.

There were two points, the speaker said, in regard to tuberculosis about which most physicians are in accord: 1, the almost invariably fatal termination of tubercular disease of the internal organs, especially of the lungs, larynx, and intestines; and 2, the infectious nature of the malady. But the experiences of physicians are of little value in enabling us to judge of tuberculosis of other organs and tissues which are found under more favorable physiological conditions and which have no direct bearing upon the preservation of life. Hence it happens that the experiences of physicians and of surgeons as regards tuberculosis differ in many points. Experimental inoculation teaches us little in respect to surgical tuberculosis, since the local disease leads to general infection in only a small proportion of cases. The number of surgical diseases met with every day, which, in the past fifteen years, have come to be recognized as tubercular in character, is now so great that the surgeon has really more to do with the affection than has the physician. For this reason, the speaker said, many problems concerning tuberculosis must fall to the surgeon to solve, and he therefore thought it expedient to present, as briefly as possible, the various affections falling in this province. The first division of his subject was

TUBERCULOSIS OF THE SKIN AND CELLULAR TISSUE.

Lupus is a sure tuberculosis of the skin, but constituting a special variety of the same, and affecting chiefly those individuals in whom there is little or no hereditary predisposition to tuberculosis. It is distinguished clinically from other tuberculous skin affections through its tendency to local relapse, and through its commencement as small brown nodules.

Tubercular abscesses are distinguished by a peculiar violet or yellowish gray membrane which constitutes their wall. This membrane attains, after a short time, a thickness of several millimetres, and is filled with countless numbers of miliary tubercles. It is easily dissected away from the neighboring tissues, which, except for a slight induration, are healthy. This membrane is found only with tubercular abscesses, and is of absolute diagnostic value.

In the discussion of this portion of the paper Herr v. Langenbeck said that he had always been of the opinion that lupus and tuberculosis of the skin were identical affections, since both showed the same bacillus.

Herr Volkmann replied that, though they were identical as regards the bacillus, there was clinically a great difference between the two conditions, and this difference was of great importance from a prognostic point of view.

Herr König agreed in the main with the author of the paper, but he did not regard the presence of a membrane containing miliary tubercles as characteristic, since a similar membrane was often formed secondarily in osteomyelitis.

Herr Doutrelepont, of Bonn, recognized a difference between lupus and other tuberculous skin affections, and agreed with Neisser in his classification of lupus, scrofuloderma, and tubercular ulcers. The latter were

met with in subjects of tuberculosis toward the end of life, and were to be regarded as secondary metastatic processes.

Herr Lassar, of Berlin, thought it unsafe to affirm that lupus was a true tubercular affection. Individuals in apparently perfect health often suffered from a circumscribed infiltration in the skin of the face, without ever becoming the subjects of general tuberculosis. And again, when this patch of lupus was scraped away it always returned, but other local tuberculosis could be cured by operation.

Herr Esmarch, of Kiel, stated that lupus often appeared in the immediate neighborhood of caseous cervical glands, scrofulous eczema of the face, conjunctivitis, and phlyctenular keratitis, which offered ready means of ingress for the bacilli. The frequent relapses after operation for lupus he thought to be due to the presence of bacilli in the sweat-glands, and could be prevented by a free use of the cautery or by excision of the entire thickness of the skin.

The second division of the paper was upon

TUBERCULOUS AFFECTIONS OF THE ACCESSIBLE MUCOUS MEMBRANES.

Tuberculosis of the tongue exists under the form of ulcerations, or as deep-seated nodules, which after a certain time become caseous in their centre. Other parts of the mouth may be the seat of tuberculosis, which is often mistaken for congenital syphilis. There is also a tuberculous ozæna due to the presence of ulcers on the nasal mucous membrane. This affection is to be carefully distinguished from the so-called scrofulous rhinitis, a very common affection and one dependent upon catarrhal inflammation. Upon the lips the author had twice seen tubercular ulcers. Fistula in ano may arise from tubercular ulcers. Fistulæ of this sort are characterized by a tendency to fungous granulation and to extensive undermining of the mucous membrane and integument. Finally perityphlitis may arise from perforation in intestinal tuberculosis.

Herr Maas, of Würzburg, said that it was often extremely difficult to distinguish between tuberculosis and carcinoma of the tongue, since the former often reached such a degree of swelling as to be readily mistaken for cancer or gumma. The prognosis of lingual tuberculosis was relatively good.

Herr König referred to a form of tuberculosis of the nose which the author had not mentioned, namely, tubercular fibroma. This was a tumor composed of fibrous tissue containing numerous tubercles. It often bore a close resemblance to a mucous polypus.

Herr Riedel, of Aachen, had removed such a growth from the nasal cavity, and a similar one from the substance of the tongue.

TUBERCULOSIS OF THE URINO-GENITAL ORGANS.

Tuberculosis of the testicle occurs with greatest frequency in early or middle age, but is not unknown even at a later period. Both testicles are usually affected, though not always simultaneously. Secondary disease of the spermatic cord presents either as an uniform thickening or as little granular swellings in the course of the vas deferens. Tuberculosis of the bladder, ureters, and kidneys was one of the most typical and serious forms of the disease. As to whether operative interference in tuberculosis of the kidney was of any real advantage to the patient, the author was not decided. The presence of tubercle bacilli in the urine offers an early and certain means of diagnosis. Tuberculosis of the mamma is of very rare occurrence. It should be treated by amputation of the breast and removal of the axillary glands.

Herr König thought a distinction should be made in tuberculosis of the testicle between the primary and secondary forms. The former is of more favorable prognosis. When the disease occurs secondarily to tuberculosis of the kidney castration is useless.

Herr v. Langenbeck was opposed to castration in children and young persons, and favored it in older individuals only when there was a great amount of suppuration. An anti-scrofulous treatment by iodine, cod-liver oil, sea-baths, etc., offered the best hopes of cure. If an operation was insisted upon, he preferred that of Malgaigne, who removed the diseased lobules, only leaving the sound portion of the testis intact. He had done this himself in one instance with success.

Herr Schede, of Hamburg, thought castration was the most certain means of ensuring against a relapse, yet in many cases it would suffice to remove the diseased portion. It often happened that the disease was a tuberculous periorchitis, and the testicle itself was but little, if at all, involved in the morbid process.

Herr Güterbock, of Berlin, had never seen a case of tubercle of the testicle in which the prostate gland, bladder, and kidneys were not also implicated. He favored castration in the case of adults when the testis was extensively diseased, yet he regarded the prognosis as bad.

Herr Volkmann did not agree with the last speaker. He had performed castration in many cases, and had obtained a definite cure.

TUBERCULOSIS OF THE BONES, JOINTS, AND TENDON-SHEATHS.

All these conditions are now, with few and decreasing exceptions, recognized as truly tuberculous which were formerly designated as caries of the bone, pseudarthrocace, spina ventosa, scrofulous inflammations of the bones and joints, white swelling, strumous joint disease, or fungous inflammations of the joints and bones. Tuberculous joint disease may begin either in the bone or in the synovial membrane; the former is more frequent in children, the latter in adults. Tuberculosis of the bones, without involvement of the large joints, is represented by the following clinical forms: 1, Spina ventosa (pseudarthrocace); 2, tuberculous suppuration and necrosis of the orbital portion of the superior maxilla with the secondary characteristic ectropion of the lower lid; 3, cold abscesses of the scalp; 4, caries of the ribs; and 5, Pott's disease of the spine. Tuberculosis of the long bones in adults almost never occurs in the shaft of the bone, and chronic osteitis and periostitis at the diaphysis may usually be referred to other causes than tubercular infection. Abscesses connected with tuberculous bone and joint disease may be freely opened under antiseptic precautions without danger. An operation for the removal of tuberculous portions of bone seems occasionally to give rise to a general infection through entrance of the virus into the blood-channels.

TUBERCULOSIS OF THE LYMPHATIC GLANDS.

In all the above-mentioned affections the neighboring lymphatic glands may become secondarily infected. In scrofulous individuals, however, there may be a hyperplastic or inflammatory swelling of the lymphatic glands which is not tuberculous. Whether there may be a caseous degeneration of the glands which is not tuberculous is as yet a matter of dispute.

Discussion on the greater part of Herr Volkmann's paper was postponed, for lack of time, to the next Congress.

Herr Braun, of Jena, then read a paper on the

OPERATIVE TREATMENT OF INTESTINAL INVAGINATION.

From a study of the statistics of the different operations the author came to the conclusion that a reduction of the invaginated portion should be attempted as soon as possible by means of laparotomy. If this did not succeed, excision of the strangulated portion or the construction of an artificial anus was to be recommended in the case of adults or of older children, but neither of these measures was permissible in very young children.

Herr Grimm, of Berlin, presented a communication on

CHYLURIA.

The author had, in conjunction with Herr J. Munk, instituted a number of experiments upon a patient suffering from this disease. They found that the fats excreted in the urine corresponded exactly to those introduced into the intestine, and they concluded, therefore, that the fluid was chyle and not lymph, as had been supposed by Manson.

Herr König, of Göttingen, then read a paper on

RESECTION OF THE ANKLE

for tuberculosis of that articulation. After passing in review the diverse opinions held by different surgeons as to the operation most suitable for disease of the ankle-joint, and detailing the indications for resection, the author proceeded to recount his method of operating. He made two incisions intended to embrace the entire anterior insertion of the synovial sac. The first began on the anterior surface of the tibia, about three centimetres (one and one-fourth inch) above the articular cartilage, curving around the joint over the neck of the astragalus, and terminated at the articulation of the astragalus with the scaphoid. A corresponding incision was then made on the other side of the joint. The flap was now turned back and the anterior surface of the tibia exposed. The anterior portion of the synovial sac was removed and the affected portion of the tibia chiselled away, care being taken, however, to leave the malleoli *in situ*. The astragalus should, if possible, be spared, as its removal increases the deformity and prevents a restoration of joint mobility. Any tubercular foci in the bone should of course be removed, but the speaker preferred to do this with the gouge and sharp spoon, rather than to sacrifice the entire astragalus. Some patients were presented to show the results of this operation.

Herr Volkmann said that all that was new about this operation was the preservation of the malleoli, but he doubted whether this contributed very much to preservation of motion in the joint. He warned against a too early resection of the joint, as the operation was by no means always necessary, and, indeed, in children was seldom required.

Herr v. Langenbeck was astonished at the favorable results obtained by the author of the paper, for his experience had been very different. He had usually found it necessary to resort to amputation in the end, and he always advised that operation in the first instance.

Herr Volkmann suggested that perhaps the better results now obtained were due to the fact that the joint capsule was entirely removed, whereas formerly it was the custom to leave the greater part of it untouched.

Herr v. Langenbeck said that he had been very careful to remove as much of the capsule as possible.

Herr König thought that his success was in great measure due to the free use of iodoform.

Herr Riedel gave the results of the resections of the ankle performed by him, and said that he favored König's operation. It was not popular because there was an impression that it was very difficult of performance, but it could be simplified without sacrificing any important details.

Herr Bramann, of Berlin, then read a paper on an operation for

VARICOSE ANEURISM.

The varix in the case reported was situated in the axilla. It was removed with some difficulty after ligature of the vessels above and below the sac.

Herr Fehleisen, of Berlin, presented a communication upon the

HIGH OPERATION FOR STONE.

He showed by a number of frozen sections that the prævesical fold of the peritoneum was pushed up farther by a distended rectum than by a full bladder. He therefore urged upon his hearers the necessity of tamponing the rectum prior to the performance of the high operation.

Herr v. Antal, of Budapesth, described a

MODIFICATION OF THE HIGH OPERATION,

which consisted in an oblique instead of a straight incision through the wall of the bladder. In this way, he contended, healing of the vesical wound by first intention is favored, since the opposing surfaces are broader and unite more readily.

Herr Maas, of Würzburg, presented a paper on

THE MEDIAN OPERATION,

which he considered preferable to the supra-pubic. The chief danger of the latter lay in the impossibility of keeping the bladder aseptic, notwithstanding thorough disinfection at the time of the operation. The median operation was safer and more easily performed and was to be the operation of the future for vesical tumors or calculi.

It was decided to postpone the discussion on the various operations for calculus to the next Congress.

Herr Sonnenberg, of Berlin, related two cases of

PARTIAL RESECTION OF THE BLADDER,

one performed for removal of a tumor, the other on account of rupture of the organ. Both patients died, and the specimens were exhibited to the Congress.

Baron von Hirsch, of Vienna, related a case of

EXTIRPATION OF THE KIDNEY.

The patient, a woman aged forty, had suffered for two years from a tumor of the right kidney. The organ was removed, and the patient made a good recovery.

The same gentleman related a case of

EXTIRPATION OF THE SPLEEN,

with a like favorable termination. Examination of the blood some time after the operation showed an increase in the number of red, and a decrease in the number of white, corpuscles.

Herr Credé said that, in a case operated upon by him some three years ago, he had found a change in the relative proportions of red and white globules exactly the reverse of that found by the last speaker.

Herr Claus, of Elberfeld, related a case of

REMOVAL OF A RENAL TUMOR THROUGH LAPAROTOMY.

The case was supposed to be one of ovarian tumor, and the diagnosis was not rectified until the abdomen was opened. The patient recovered. The author referred to the statistics of v. Bergmann, according to which, of twenty-four laparotomies for extirpation of tumors, there were twenty recoveries, and he thought that the proportion of successful cases would continue to increase.

Herr König had performed abdominal section twice in the past year for tumor of the kidney. He had made a large incision through the posterior layer of peritoneum, and experienced no difficulty in completing the operation.

Herr Claus thought it was easier to remove a tumor of the kidney than an ovarian cyst, since the adhesions in the former case were not so close.

Herr Schönvorn related another case in which he had successfully performed this operation.

Herr Landau was opposed to extirpation of the kidney for hydronephrosis. He much preferred the establishment of a fistulous opening.

Herr J. Wolff, of Berlin, read a paper on

URANOPLASTY AND STAPHYLORRHAPHY.

He related a case in which he had successfully closed the cleft, but without obtaining any improvement in the voice. This had led him to the construction of an obturator made of rubber which could be inflated whenever desired, and by means of which the patient was enabled

to speak with a natural voice. He thought that in such cases, in addition to the operation and the use of the obturator, it was necessary to train the patient to speak in a natural way.

Herr König spoke in praise of the obturator, and instanced one case in particular in which the most brilliant results were obtained from its use.

Herr v. Langenbeck thought that the trouble was often in the palatal muscles, and advised the use of electricity without the obturator.

Herr Rydygier thought that proper training in articulation and lip movements was the most important thing.

Herr Schede agreed with the last speaker, and said that he was often astonished to note the improvement in patients in the course of a year. Time and training were absolutely necessary.

Herr Winiwarter recommended a sort of massage of the lips and pharyngeal muscles in addition to the other methods. He had never been obliged to use an obturator in his cases.

Herr Gärtner read a paper on the

DISINFECTANT ACTION OF WATERY SOLUTIONS OF CARBOLIC ACID.

The author had made experiments to determine the destructive action of carbolic acid upon various forms of micro-organisms, and concluded that a three per cent. solution was sufficient to kill every form of inferior organism with which the surgeon had to do. The disinfectant must, of course, be brought into actual contact with the microbes.

Herr Kümmel then presented a communication, entitled,

INFECTION BY CONTACT AND THROUGH THE ATMOSPHERE IN PRACTICAL SURGERY.

He detailed a number of experiments showing that immersion of instruments for a brief period in disinfectant solutions was often insufficient to render them aseptic. He advised that they be first washed in ether, or warm water and soap, and then laid in the antiseptic solution. Infection through the air was not so greatly to be feared in ordinary cases, yet it was impossible to obtain an atmosphere entirely free from micro-organisms.

Herr v. Bergmann read a paper on

COMPRESSION OF THE BRAIN SUBSTANCE,

in which he opposed the views of Adamkiewicz.

Herr Tillmanns, of Leipzig, presented a communication on

OSTEOMA OF THE NASAL CAVITY,

and another on the

UNION OF SEPARATED NERVE ENDS.

In cases in which the two ends of a divided nerve were separated widely, he had succeeded in restoring its function by cutting strips from each end, leaving them attached at one extremity, turning them over so as to overlap each other and then uniting them by suture.

Herr Albrecht, of Brussels, read a paper on the

MORPHOLOGICAL SIGNIFICANCE OF PHARYNGEAL DIVERTICULA.

These existed normally in certain quadrupeds, and hence the author concluded that Ziemssen and others were wrong in attributing their occasional presence in man to the effect of pressure from a foreign body or of retraction from a cicatrized gland.

Herr v. Hacker presented a communication on

RESECTION OF THE STOMACH AND GASTRO-ENTEROSTOMY.

He advised, in cases in which the tumor was movable, that both the stomach and the duodenum be closed, and that communication be established through a gastro-cæcal fistula. He related a case in which he had performed this operation with temporary success, although the patient had begun to have trouble again and was probably suffering from a return of the carcinoma.

Herr Lauenstein then read a paper on

RESECTION OF THE PYLORUS.

He recommended the employment of the continuous suture as one that would save much time in the operation. He also thought it preferable, when adhesions were present, to ligate and divide the duodenum first, and then to dissect away the adhesions.

Herr Kraske read a paper on

EXTIRPATION OF CANCER OF THE RECTUM.

In those cases in which the disease was located so high as to preclude the possibility of extirpation from below, he had succeeded by removing a portion of the sacrum.

Herr Bessel Hagen then read a communication on

EXSECTION OF THE ASTRAGALUS IN CLUB-FOOT.

The author favored total extirpation of this bone in both congenital and acquired talipes. He exhibited two cases in which he had overcome the deformity by means of this operation, although the patient walked with a decided limp.

Herr Hirschberg did not think that this was the best operation for talipes. He removed a wedge-shaped piece of bone and believed that he thereby obtained better results.

Herr J. Wolff did not regard extirpation of the astragalus with favor. He thought club-foot could be cured without this and exhibited a case in support of his opinion. The patient was nineteen years old, and the only operation performed was tenotomy of the tendo Achillis.

Herr Kümmel presented a paper on

OSTEOPLASTIC RESECTION OF THE FOOT.

The scientific work of the Congress was now completed, and the only remaining business was the

ELECTION OF A PRESIDENT.

Professor v. Langenbeck having consented to accept a renomination, he was re-elected by acclamation. The Congress was then declared adjourned.

ILLINOIS STATE MEDICAL SOCIETY.

Thirty-Fifth Annual Meeting, held at Springfield, Ill. May 19, 20, *and* 21, 1885.

(Concluded from page 580.)

THIRD DAY—THURSDAY, MAY 21ST.

The meeting was called to order by the President at 9 A.M.

The following officers were elected: Dr. W. A. Byrd, of Quincy, President; Dr. W. T. Kirk, of Atlanta, First Vice-President; Dr. A. Wetmore, of Waterloo, Second Vice-President; Dr. S. J. Jones, of Chicago, Permanent Secretary; Dr. Herman Luce, of Bloomington, Assistant Secretary; Dr. Walter Hay, of Chicago, Treasurer.

Dr. Kreider, of Springfield, read a paper on "Education Preliminary to Study of Medicine," which drew out considerable discussion by Drs. Mileham, Byford, Jr., Wetmore, Earle, and others, and was referred to the Committee on Publication.

Dr. Waxham, of Chicago, read that portion of the report on Practice of Medicine which referred to intubation of the larynx, with exhibition of the tubes used.

The remainder of the report, which was read by Drs. C. W. Earle and W. T. Montgomery, of Chicago, referred favorably to the use of hydrochlorate of cocaine, trypsin, and other new discoveries. The report, in referring to the treatment of typhoid fever, went to show that about as good, if not better results were obtained by the expectant plan of treatment as by specific remedies. The whole report was received and referred to the Committee on Publication.

Dr. Norred, of Lincoln, read a paper on

THE DOCTOR IN COURT,

which was received and referred for publication.

THE REPORT OF THE COMMITTEE ON SURGERY

was next read by Dr. W. A. Byrd, of Quincy, in which he reported a method of amputation at the hip-joint without hemorrhage, by the use of an elastic tourniquet, having himself operated on two patients in that manner without loss of blood and with one recovery, the other case living four days. He also reported a case of psoas abscess, which he opened below Poupart's ligament, and passed a long probe up to the seat of the abscess through the opening. He then cut down in the lumbar region on to the point of the probe, thereby secured free drainage, and got good recovery. The report otherwise contained a general *résumé* of the last year's progress in that branch.

The report was received and referred for publication.

Papers on "Obstruction of the Bowels," by Dr. W. H. Veach, of Carthage; "Ophthalmology," by Dr. Robert Tilly, of Chicago; and on "Simple Renal Catarrh," by Dr. I. N. Danforth, of Chicago, were read and referred for publication.

The Society then adjourned, to meet at Bloomington on the third Tuesday of May, 1886.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 25, 1885.

Daniel Lewis, M.D., President, in the Chair.

The *Comitia Minora* made its final

REPORT ON THE QUESTION OF RESIGNATION,

and that members can resign by complying with Art. 6, Chapter XII., of the By-laws of the Society. The report was based upon action taken by the Medical Society of the State of New York with reference to the same question, and included the opinion that a member "can voluntarily sever his connection by resignation or withdrawal, but by so doing he puts himself into the position in which he is liable to the infliction of the penalties prescribed by the statutes; that is, that his license becomes forfeited, and he is subject to the consequences of such forfeiture."

The report was accepted and adopted.

NON-PAYMENT OF DUES.

The *Comitia* also recommended that the names of all members in arrears in dues three years be dropped from the roll.

Dr. Roosa moved as an amendment, that this recommendation applies to all except to those members whose dues the *Comitia* may unanimously remit. Carried.

The recommendation of the *Comitia* as amended was adopted.

Dr. George A. Seibert read a paper on

THE ATMOSPHERICAL RELATIONS OF FIBRINOUS PNEUMONIA.

The paper was a report based upon collective investigation under the auspices of the Committee on Hygiene, and contained the substance of information derived from general practitioners, from statistics from the German and Austrian armies, and from German hospitals, etc. It was illustrated by elaborate charts.

The results of those observations were embraced in the following conclusions:

1. The origination of fibrous pneumonia is greatly favored by certain meteorological conditions, thus explaining the difference in the frequency of its occurrence during the twelve months of the year.

2. A low or falling temperature, a high or rising humidity, and high winds, are each one capable of exerting this influence.

3. If two of these weather constituents are found together, high wind and cold air, or falling temperature and high wind, etc., more cases of pneumonia occur than when either atmospherical condition is found alone.

4. If these three constituents are found together, then the frequency of pneumonia will be found astonishing.

5. The frequency continues to follow as long as these conditions prevail.

6. The same meteorological influence is found to originate bronchial catarrh, and the existing catarrh predisposes to fibrinous pneumonia.

Dr. Seibert did not claim that fibrinous pneumonia was or could be brought on by weather influences alone.

The discussion was opened by Dr. A. Jacobi, who said that remarks on the question were unnecessary, because the report and the charts by which it was illustrated, contained simply facts, undoubtedly well founded, bearing on the etiology of the disease. He had been specially interested because of the relation which Dr. Seibert's labor sustained to the projected work of the International Medical Congress instituted at Copenhagen last year, and of which this and other societies would hear more presently, and would be asked to co-operate in carrying out the plans of the Congress.

Dr. Jacobi then spoke of the relation which pathology, microscopy, bacteriology, and clinical observation bear to each other, and believed that it was only when they were combined and their united efforts closely analyzed, that the best results could be obtained.

Dr. A. G. Caille said that if the author of the paper meant that there might be other causes of fibrinous pneumonia than atmospherical, then he could agree with him; but if he meant that exposure to cold never caused pneumonia, but only catarrh, then he disagreed with him.

Dr. Putzel called attention to the fact, seemingly well established, that pneumonia was an acute infectious disease; that many conditions might enter into the etiology that had not been discussed. He believed that temperature and humidity were not sufficient of themselves to cause the disease.

Dr. Seibert said that he had abstained from theorizing in his report. What he had given were facts as he had found them, and they must be taken as they were. In connection with Dr. Putzel's remark, he would refer to Jürgensen, who laughed at the results reached in his first report on this question, but a year later acknowledged that he was mistaken, and then reported that, out of seventy autopsies after pneumonia, he found catarrh in sixty-eight cases.

Without giving any theory, Dr. Seibert said his belief was, and yet he was unable to prove it at present, that atmospherical influences caused a catarrhal hyperæmia of the bronchial mucous membrane that prepared the patient for the poison of pneumonia; that there was no pneumonia without preparatory catarrhal hyperæmia; that pneumonia was not due to weather influences alone, but that they have a decided influence in the origination of the disease.

Dr. Caille moved that a vote of thanks be tendered to Dr. Seibert for his valuable report. Carried.

Dr. C. Heitzman then delivered a worthy

MEMOIR OF LOUIS ELSBERG, M.D.,

and on motion by Dr. Leszynsky the thanks of the Society were tendered to the memorialist.

Dr. Joseph W. Howe was elected a delegate to the British Medical Association.

Dr. O. B. Douglas offered a preamble and resolutions tendering the thanks of the Society to Hon. J. S. Van Duzer, member of Assembly from Chemung County, for his invaluable aid and persistent efforts in behalf of all measures affecting the Medical Society of the County of New York, during the last session of the Legislature. Unanimously adopted.

The Society then adjourned to meet in September.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 21, 1885.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

PHYSICIANS DO NOT REPORT CASES OF CONTAGIOUS DISEASES.

THE PRESIDENT read a letter received from Dr. E. H. Janes, of the Board of Health, calling attention to the fact that many physicians had failed to report cases of contagious diseases to the Board until after death, and further to the effect that the Board did not desire to prosecute those physicians if the neglect to comply with the law could be corrected by milder means.

DR. T. HERRING BURCHARD then read a paper entitled

OBSERVATIONS ON THE TREATMENT, MEDICAL AND SURGICAL, OF ACUTE PERITONITIS.

Peritonitis might well be regarded as the most fatal of the acute inflammatory diseases. After a careful compilation of various hospital statistics, etc., its mortality might be set down when all varieties of the disease were considered, at about from fifty to sixty per cent., and from twenty to thirty per cent. higher when so-called "idiopathic cases" were excluded.

All treatment to rise above mere empiricism must rest upon a three-fold conception—a conception of the cause of the disease, a conception of the natural history of the disease, and finally the natural tendencies of the disease, or a foreknowledge of the mode of recovery or death.

It would suffice to know that peritonitis might originate from *external traumatisms*, from *internal traumatisms*, by extension of inflammation from contiguous parts, from septic causes and certain blood diseases (as rheumatism, Bright's, etc.), and possibly, though rarely, from causes that were purely miasmatic and climatic, constituting the so-called idiopathic cases.

What were the causes of death? According to the text-book, collapse and asthenia. According to clinical and pathological observation, first, *collapse;* second, *asthenia*, which might be more intelligently expressed by (*a*) heart-failure, (*b*) respiratory failure; third, by inflammatory changes in the lungs; fourth, by inflammatory changes in the kidneys; fifth, by hyperpyrexia as a special cause superinducing any or all the above.

In no other disease was an early knowledge of the causation of the attack so essential. It was in the incipiency of the attack, before excessive tympanites had disturbed the normal configurations of the abdomen and fatal asthenia had developed, that the golden opportunity for successful diagnosis existed.

Under a systematically conducted examination, which necessitated the interrogation of each abdominal viscus, and which sought to find a satisfactory explanation for each abnormal symptom, it was surprising how the difficulty would disappear. It was to a want of thoroughness in the examination and a lack of the judicial element in weighing symptoms, rather than to inherent difficulties, that the diagnosis often seemed so obscure.

The diagnosis being made, and a local lesion amenable to surgical interference being demonstrated, surgical relief should be rendered at the earliest moment practicable.

What, under the circumstances, were the indications for treatment? Were the irritation located elsewhere in the body than in this much-dreaded locality, sound surgical judgment would advise the immediate removal of the irritant. Why, then, should the peritoneum, a region which was daily proving its immunity to surgical manipulation by giving to surgery its brightest triumphs, not be subjected to the same wise principles that guided us elsewhere in our operative procedures?

Dr. Burchard then referred to the paper read in this very hall, by J. Marion Sims (*British Medical Journal*, December 17, 1881), who sounded the keynote of the future treatment of such cases when he said, "Given a case of perforation of the intestines, and given an accurate diagnosis, which is by no means difficult, what are we to do in the present state of our knowledge? Why, of course, we should open the abdomen promptly, clean out the peritoneal cavity, search for the perforation, pare its edges and bring them together with sutures, and treat the case as we now treat other cases involving the peritoneum. "Rest assured," he says, "that the day will come—and it is not far off—when an accurate diagnosis in such cases followed by prompt action will save life that must otherwise quickly ebb away."

The point raised by Dr. James R. Wood, in the discussion on Dr. Sims' paper, to which reference had already been made, viz., that "pathological surgery, or operations done for tumors and disease, was very different in its result from traumatic or acute surgery, and that this was specially true regarding manipulation of a large serous membrane that resents all impertinent interference," did not, it seemed to him, afford a sufficiently logical basis for doing or not doing the operation. As a clinical fact, the peritoneum was exceedingly tolerant of interferences, provided the proper precautions were observed.

Dr. Burchard then read the histories of forty cases of laparotomy performed for injuries done to the abdominal viscera, either from external or internal violence, many of which were suffering at the time of the operation from acute peritonitis, including sixteen in which the operation was performed for the relief of acute peritonitis with purulent collections. The following is an abstract of the above cases: Laparotomies performed for internal traumatism, 21, with 12 deaths and 9 recoveries; laparotomies performed for external traumatism, 3, with 1 death and 2 recoveries; laparotomies performed for peritonitis, 16, with 3 deaths and 13 recoveries.

After which he read the history in full of his own case, which occurred in a man, twenty six years of age, in whom an omental abscess burst into the peritoneal cavity during an acute peritonitis. Laparotomy was done, and the patient made a good recovery.

If these 40 cases with 24 recoveries teach anything, they teach not merely the feasibility of such operations, but, more than that, they give us legitimate ground for encouragement in fully sixty per cent. of these otherwise hopeless cases.

THE MEDICAL TREATMENT OF PERITONITIS.

Concerning this there were some points of special interest, and first, the opium treatment, which, while it was our sheet-anchor in the treatment of peritonitis, there were certain conditions in the course of the disease in which the drug could only be used with the greatest caution. The indiscriminate use of opium, even in peritonitis, was quite capable of doing more harm than good.

The symptoms of peritonitis varied with its extent, severity, and the causes which produced it. When the disease developed gradually, as from a pre-existing visceral inflammation, for some time there might be little or no constitutional disturbance. When it developed suddenly, however, and particularly if from internal traumatism, as hernia, perforation, or other intestinal injury, the condition of shock entered as a very important element in the development of symptoms, and the treatment must be varied accordingly. This initial collapse of peritonitis was a subject upon which too little has been said, and yet its treatment was of most signal importance.

In speaking of treatment, the text-books generally recommended that "as soon as the unmistakable symptoms of peritonitis were developed, at one dose from two to five grains of opium be given, or from one-half to one grain of morphine."

But collapse was a condition of the system in which opium, even in moderate doses, was poorly borne. Infinitesimal doses of morphine in conjunction with atropia, by mitigating pain and securing nervous tranquillity, undoubtedly exerted a favorable tonic influence upon the

heart. Large doses increased the paralysis of the cardiac inhibitory centre, and still further crippled that organ.

Another and very important fact to be noticed in the commencement of peritonitis—and governing greatly the freedom with which opium may be used—was the perplexing discrepancy that ofttimes existed between the severity of the pain and the apparent hard-time wiry pulse on the one hand, and on the other the very great heart-feebleness. Under such circumstances every dose of opium given, unless guarded by atropia or digitalis, jeopardized the heart, and no dose should be administered under such circumstances without previous careful cardiac auscultation.

There is another condition, developing later in the history of the disease, in which the administration of morphia in large doses was equally prejudicial; and upon which condition current literature is likewise, unfortunately, silent—namely, hypostatic pneumonia, which, owing partly to the patient's asthenic condition and partly to pressure on the lungs from excessive tympanites, was so apt to develop at that time. At this stage a slight over-dose of morphine might arrest entirely the respiratory act.

Regarding the use of opium, freedom from pain was the ideal condition to be secured, irrespective of the quantity of the drug administered. When this was attained, sleep, from which a patient could be readily aroused, followed as a natural consequence. Opium, or its alkaloid morphine, should be administered. Personally he preferred the hypodermic administration of morphine, not alone from the simplicity and certainty of its administration, but what was of more consequence, the absolute knowledge it gave of the exact quantity of the drug the patient was receiving.

Objections had been raised against the combination of atropia with morphia. Undoubtedly, atropia did produce a marked change in the patient's appearance, and certain very characteristic changes in the phenomena of the disease, but these changes, he believed, were in every way favorable to the patient. There was no one drug, in the treatment of collapse, whatever be its cause, whether traumatic or from disease, in which more implicit confidence could be placed than in atropia.

EXTERNAL APPLICATIONS.

Much had been said of the efficacy of external applications, used either hot or cold. Poultices were still used by many. Until within the last two years, he employed them exclusively. Upon what therapeutic principle their use was based he didn't know then, and don't know now. Poultices are not curative.

Cold, judiciously employed, lowered temperature, reduced inflammation, relieved tympanites, and secured nervous tranquillity. There was but one way of employing cold, and that was by the *ice-coil*. This could be readily extemporized from either lead or rubber tubing.

DIET.

For diet nothing was comparable with peptonized milk, to which additional cream might be added if desired.

TYMPANITES.

For the relief of tympanites much depended upon whether the gas was within the cavity of the peritoneum or in the intestines. If the former, a fine aspirating needle might be introduced and with immediate relief; if the latter, a long tube might be passed up the bowel and an ounce or more of some warm aromatic solution injected. Gas must not be expected to escape through a tube occluded with fæces. Pneumatic aspiration of the intestine he regarded as neither surgical nor safe. Turpentine stupes he resorted to, more out of respect to a tradition than because of any very positive benefi the had ever seen follow their use in general peritonitis. When turpentine was pushed to any considerable extent, he feared damage to the kidneys.

Last, but by no means least, the successful treatment of peritonitis demands a personal devotion and attention involving complete abnegation of self.

The discussion was opened by Dr. A. L. Loomis, who said it hardly seemed proper that a physician should be called upon to discuss a surgical paper, yet his interest in the subject, and the frequency with which he had urged surgeons to undertake to save the life of patients with acute peritonitis, was his excuse for making a few remarks. The first important point before any surgical procedure should be resorted to was to determine exactly, if possible, the cause of the peritonitis. He was one of those who did not believe in idiopathic peritonitis, and he had not seen a case in which he had been unable to find either a local or a constitutional cause.

All the cases could be grouped under three general heads: First, constitutional, in which the peritonitis, either acute or chronic, depended upon blood-poisoning of some kind; second, those in which the inflammation extended to the peritoneum; third, those which depended upon ulceration and the discharge into the peritoneal cavity, of intestinal contents, the contents of abscesses, cysts, etc.

As to the cases in which there was intestinal perforation as a cause, he had yet to see one in which recovery had taken place after intestinal gases had entered the peritoneal cavity. He recognized this as one of the most certainly fatal causes of peritonitis, but it was often difficult to determine exactly the point where such an opening into the intestine had been made, or what portion of the intestine was involved. He did not believe that by localizing the usual symptoms of peritonitis the portion of intestine involved could always be determined, because the normal position of the abdominal contents was very likely to be changed by a variety of causes, such as displacements following old peritonitis, etc.

If, however, the exact portion of the intestine involved could be determined—that is, the exact starting-point of the peritonitis—he could readily approve of all that had been stated concerning the adoption of surgical procedure in acute peritonitis. He believed that he had seen more than one case; indeed, he had recently seen a case occurring in a member of our own profession, in whom he believed that, if an operation had been performed when he first saw the patient, there would have been a good probability of his being alive to-day, for the symptoms were not active when he first saw him. In all these cases, when ulceration had taken place and symptoms were slowly developing, there were almost always signs of localized peritonitis, and these were fixed pain, increased by firm pressure, arrest of abdominal respiration, and a feebleness of heart-power which did not correspond to the amount of peritonitis. With such symptoms, and the condition manifesting itself locally in the right iliac fossa, it seemed to him that the surgeon would be justified in cutting down and preventing the fatal peritonitis which would develop when a perforation occurred: or, if not to do that, to stand by the patient and be ready, as soon as the first symptoms of perforation did occur, to proceed with the surgical operation and open the peritoneal cavity. In two or three instances he had stood by surgeons and urged them to open the peritoneal cavity and endeavor to find out the cause of peritonitis. In one hospital case, in which he specially urged the propriety of this procedure, the autopsy proved that there was a narrow fibrous band constricting a portion of the small intestine, which might have been easily divided and the obstruction relieved. It seemed to him that the experience of surgeons proved that it was not so dangerous to interfere with the peritoneum as had heretofore been supposed; but when there was general peritonitis with shock and collapse, the pulse 160, respirations altogether thoracic, then if an operation were performed the chances of success were very small. It was in the early

stage that an operation was indicated to obtain a knowledge of the cause at the earliest possible moment, and so thoroughly convinced was he upon this point, that, if he felt sure of the existence of this condition in his own person, he would find some surgeon to open his abdominal cavity immediately. It was true that some patients recovered without the formation of abscess, and some recovered after the formation of abscess; but they were so few in comparison with the number in which death took place that he thought the points brought forward by the author of the paper were well taken.

With regard to the opium treatment of peritonitis, those who knew of his practice knew well that he believed in it; but he believed in it with restrictions, and all the restrictions set forth in the paper were important and should be borne in mind. Indiscriminate use of opium at first was dangerous, and it should always be guarded by the use of atropine. When the first stage of the peritonitis had passed, and the symptoms had become established and were pursuing their course steadily, then the free use of opium was indicated, and he was not so particular with reference to the combination with atropine.

The discussion was continued by DR. R. F. WEIR, who said that in many of these cases the surgeon was called upon to exercise his art as directed by the diagnostic skill of the physician. He thought Dr. Loomis had touched the key-note in the statement that there was no such disease as idiopathic peritonitis. He would also go further perhaps than the author of the paper, and would say that no case of peritonitis should be allowed to die without an exploratory incision into the peritoneal cavity. He thought this statement had as much value as it had in connection with cases of strangulated hernia.

An important paper had been written upon this subject recently by Dr. Treeves, of London, in which he had proven that in nearly all these cases of local inflammation involving the vermiform appendix, perforation took place into the peritoneal cavity, and the idea that there was a meso-colon which led to the formation of connective tissue behind the peritoneum was incorrect, and the author insisted that surgical interference in cases of so-called perityphlitic abscess should be earlier than has been heretofore resorted to.

It had been the practice among surgeons to wait until pus in these cases could be obtained by the hypodermic needle, but Dr. Weir thought that this was wrong, and that operative interference should be resorted to earlier.

But a very grave question arose. Could a surgical operation be resorted to in the condition of collapse? Experience in this direction had not been large. Two important cases had been reported, one by Mikulicz and the other by Kocher, in both of which the abdomen was opened and the patients recovered. Of course, in traumatic cases, we could not tell positively whether the collapse was due to the first invasion from the intestinal gases or from hemorrhage, and therein was exhibited the value of an exploratory incision. In twenty-four cases in which Billroth had made an exploratory incision and closed the wound all of the patients recovered, and Mr. Tait reported that of ninety-four cases of exploratory incision only three terminated fatally. An exceedingly important feature of the exploratory incision was that it enabled us always to say when *not* to do anything. He was entirely in accord with the author of the paper with reference to the propriety of surgical procedure at the onset of the disease.

THE PRESIDENT said it might be a question whether in every case of perityphlitis an operation should be performed very early. He believed that all were not fully prepared to operate at once, even though a diagnosis was satisfactorily made, simply because it was well known that in a large number of cases the local inflammation had remained localized. It was also known that recoveries from perityphlitis took place, and recoveries also after the perityphlitis had become general peritonitis. For the general practitioner it was certainly a very responsible position and an important question to decide whether he should advise an operation at once or whether there were not sound reasons for waiting perhaps for some time. He had seen such a case within the last two weeks, that of a boy sixteen years of age, with all the history of peritonitis, sudden pain, localized swelling, some dulness on percussion, slight elevation of the thigh, moderate amount of fever, but no collapse, and the condition confined to the right iliac region. There was typhlitis, and the question arose whether an operation was justifiable at once, or whether the case should be permitted to go on for awhile. The treatment consisted in the use of morphine combined with atropine, and local application of ice, ice, ice. The peritonitis became general, but the general symptoms were not urgent; the temperature was usually about 102° F., often below, only once reaching 104° F.; there was thoracic respiration and extensive pain. Even in that case he hesitated to propose an operation, because the general condition of the patient appeared to be such as to justify a little further delay. The question would be whether, when the operation was not proposed, there would be just blame and reproach due to the physician. Here was one of the difficult points to decide whether the operation should be performed or not. He had seen recovery take place in several such cases, and still further he fully agreed with the statements which had been made that there was scarcely any such thing as idiopathic peritonitis. But even after having listened to the paper of the evening and to the remarks which had been made, he was not prepared to say that he should propose laparotomy at once; he should propose it in every case where it set in suddenly—within a few hours, half a day, or perhaps a day—after a diagnosis of perityphlitis had been made; but when the progress of the case was slow, he still would hesitate to recommend the operation.

With regard to the time when the operation should be performed, Dr. Loomis had recommended that it be resorted to when the first signs of perforation occurred. Dr. Jacobi believed that the perforation was frequently the first thing which did occur, when the patient was suddenly attacked with acute pain repeated in instalments, although there were undoubtedly changes in the intestine before that; but the sudden pain was simply a symptom of perforation. He believed that a large number of cases began with perforation. He should propose an operation in every case where peritonitis sets in very suddenly after perityphlitis had been diagnosticated.

DR. LOOMIS wished to say that the surgeon should be prepared to perform the operation as soon as the evidence of perforation had appeared. He should beg to differ with the statement that perforation was the beginning of perityphlitis. The case to which he referred was one in point. On a Thursday morning he saw the patient with localized pain in the region of the ileo-cæcal valve. There was scarcely any elevation of temperature, and only slight acceleration of the pulse, but there was the facies which indicated some serious form of disease. On Friday morning the patient was so well that he got up, and said that he felt all right, but on Saturday morning there was a sudden collapse, and the signs of general peritonitis followed immediately. At the autopsy there was a large quantity of lymph, nearly half an inch in thickness, surrounding the portion of vermiform appendix where there was a slough. All the intestines about that point were covered with a thick layer of plastic material which was evidently two or three days old, and there was evidence of recent general peritonitis, showing that for the first two days the peritonitis was unquestionably localized, and that there was no free communication with the peritoneal cavity, and it was during that time that the surgeon should be urged to operate.

Again, the history of repeated attacks was one with which all were familiar, and if the operation were performed at the first attack there was no doubt that the

patient would not be exposed to the danger of a second attack, perforation, and sudden death.

The President would like to ask Dr. Loomis if there were not in many cases several such perforations? Did we not often find several small perforations, and finally a very large one? Did not Dr. Loomis remember cases, seen at autopsies, in which there was a large amount of exudation of lymph, and below it traces of a small perforation; or had he not seen cases in which general peritonitis had followed perityphlitis, and in which the patient lingered on for some time, appearing to get better, and all at once new symptoms of perforation developed, attended with collapse and death? It was to be remarked that the cases differed so much in appearance at the autopsy that the clinical histories must also vary very considerably. He could not help believing that, in most cases, a small perforation was the first thing which occurred. When the perforation was large, collapse might set in at once, but when it was small it might heal, and the most urgent symptoms might not develop until very much later, if they developed at all.

Dr. Weir said that in urging earlier operative interference for ordinary forms of perityphlitis, he did not mean to resort to laparotomy, but to make the ordinary incision, and to put in a drainage-tube instead of waiting for the more complete development of the abscess.

Dr. Loomis said that at the beginning of his first remarks he stated that there was nothing so fatal as an escape of the intestinal gases into the peritoneal cavity. He could understand how the vermiform appendix might be closed at the intestinal opening, and that ulceration further on might set up an inflammation in the connective tissue which would give rise to thickening and the formation of a tumor, etc.; but where the ulceration was sufficiently near to allow of the escape of the intestinal gases into the peritoneal cavity he could not see how it was possible not to have general peritonitis.

Dr. Burchard, in closing the discussion, referred to six cases of typhlitis and perityphlitis which he had already reported, accompanied by perforation, and in five he had the opportunity to verify the diagnosis by autopsy. In every one of these cases, before the perforation which caused the death of the patient, there was a history of one or more attacks of perityphlitis. He believed that that was strong evidence with reference to an absolutely positive diagnosis. If a patient was found in collapse or partial collapse, who gave a history of preceding typhlitis, he believed that the surgeon was justified in the interference, that the patient was suffering from perforation of the intestine, especially so if the attack had been preceded by constipation, as was almost always the case, and almost without exception the acute symptoms had followed the taking of some active purgative.

The rapidity with which the collapse developed gave an important clue to the nature of the injury which the gut had received. If there was only slight collapse it might be inferred that, if there was perforation, it was so minute it could not be diagnosticated at all; if collapse was very profound and developed rapidly, we were justified in the inference that perforation of considerable size had taken place.

The Academy then adjourned.

Medical Prizes.—The Société Protectrice de l'Enfance de Lyon offers two prizes, to be awarded in 1886 and 1887 respectively, for the best essays on the following subjects: 1. On the different methods of vaccination: the age at which it is proper to vaccinate; and the prejudices against vaccination which are to be overcome. 2. On the influence of maternal occupation upon the fecundity of women, the course of pregnancy, and the vitality and health of the infants. The prizes will consist of gold medals, and the competing essays are to be given to the Secretary of the Society by the end of January in each year.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PRACTICE OF MEDICINE.

Stated Meeting, May 19, 1885.

Alfred L. Loomis, M.D., LL.D., Chairman.

Dr. Andrew H. Smith read a paper (see p. 589) entitled *Irregular Manifestations of Malaria.*

The discussion was opened by Dr. E. D. Hudson, and was continued by Dr. L. Emmett Holt (see p. 591).

The hour for closing the discussion having arrived, the topic for general discussion by the Section was taken up:

"THE SOURCE OF INFECTION AND LIMITS AS TO TIME OF INFECTION OF SCARLET FEVER AND MEASLES."

Dr. R. C. M. Page said the two diseases under discussion, measles and scarlet fever, were variously described by different authorities as being contagious or infectious, or both. All agreed, however, that neither originated spontaneously. The source of infection or contagion, therefore, must lead back to some infected individual from whom the poison had been conveyed. There were various ways in which the contagious principle might be transmitted, not to mention inoculation and actual contact or close proximity to the patient; that is, these diseases might be conveyed in fluids, such as milk, etc., or in clothing, upholstering, etc., which had been saturated with the poison of the sick-room. Nurses and others more or less constantly in contact with such patients were much more likely to carry the disease about than were physicians, who made only occasional visits, and generally aired their clothing before seeing other patients. Animals were also said to be capable of carrying the poison about, a notable instance of which had been related in Dr. Loomis' recent work on "Practice of Medicine." It was also probable that the poison of scarlet fever, in some instances at least, might be conveyed from one house to another along sewer-pipes which admitted the infection without allowing its free exit, and thus there originated what had been regarded as new sources of infection.

In 1832 Percival, of London, called attention to the possibility that man might become affected from a similar disease occurring in horses. During the past year Dr. J. C. Peters, of this city, had written more fully on that subject, and had brought forth additional evidence in support of the theory advanced by Percival.

The sources of infection of the two diseases were comparatively well known, but the limits as to time had not been so clearly defined. The susceptibility to the contagious principle of measles was much more general than to that of scarlet fever, but the poison of scarlet fever was much more durable than that of measles. In Reynold's "System of Medicine" reference had been made to a case where the person became infected from the use of a flannel bandage twelve months after it had been worn by a scarlet fever patient; also, further, where a patient was poisoned through the medium of a cloak which had been packed away for eighteen months. These cases brought to his mind one occurring in the practice of the late Dr. F. D. Lent, where the poison of diphtheria was carried from this city to Pulatka, Fla., by means of clothing of a diphtheritic patient.

The question then naturally arises. Are physicians likely to carry these diseases about with them and infect other persons? Dr. Page had never known an instance of this kind, and had always acted in these as in other diseases in going from one patient to another. But there should be an exception made in obstetric practice, especially in those cases requiring instrumental delivery.

It had been stated on good authority that after surgical operations, or after severe injury and shock, the liability to the transposition of scarlet fever was increased. In those cases, therefore, he thought physicians should be particularly careful in changing their clothing, and in other ways disinfecting themselves, if called upon to de-

liver a woman with forceps soon after having examined a scarlet fever patient. In ordinary cases such extra precautions appeared to be unnecessary. He would, however, suggest that visits to such patients should be as widely separated as possible.

Dr. C. E. Billington said that it was difficult to bring forward facts bearing upon the points under discussion which were sufficiently definite to be of positive value. With regard to the limits of time during which the disease is communicable, he thought they were quite well settled, and he had already given his views on this point in another place.

It had seemed to him that the uncertainty of the contagion of scarlet fever was an important point. Of ninety cases occurring in families where there had been more than one child sick with the disease, he had found that forty-seven had escaped. Of these forty-seven, four were so young as to render it improbable that they would have contracted the disease under any circumstances, and this left forty-three patients who had not taken scarlet fever. The practical point which he had in view in making these observations was with reference to the question of prophylaxis. If any preventive remedy had been used among these children it would have probably been considered as a triumph for the drug employed.

One point in the consideration of these two diseases was the fact that measles usually goes through an entire family, while the occurrence of isolated cases of scarlet fever was not uncommon.

With reference to the time which elapses between the exposure and the development of the disease, he had seen cases which led him to believe that it was sometimes exceedingly short, not more than twenty-four hours having elapsed after the exposure before well-marked symptoms of the affection were developed.

Dr. Billington then referred to a case occurring in the person of his assistant at the out-door department of the Demilt Dispensary, who had been repeatedly exposed to the poison of scarlet fever and had escaped, but while attending a patient who had scarlet fever with very severe anginal symptoms, and in a small, close room, he was attacked with scarlet fever, which developed within four or five days after seeing this child. At the time of making his visits the physician had a coryza, and had had one attack of epistaxis.

The Chairman remarked that there were two points worthy of special consideration: First, the time which will elapse before one with scarlet fever or measles can communicate the disease, and second, how long shall children be kept away from home or prevented from coming in contact with those who have had either of these diseases.

Dr. Page inquired whether any physician had ever carried the diseases about with him.

Dr. Hudson contributed one case, and gave the history, in which, after having visited a patient in whom the desquamation of measles was exceedingly abundant, he communicated the disease to a person who had not been exposed to measles in any other way. He had always made it a rule, after having visited a patient sick with measles or scarlet fever, to make a circuit in the open air, and on arriving at home, before seeing any of his own children, to take special pains to sponge his clothing with carbolized water, also to brush his hair with the same and to take a sniff into the nose, and in this way he thought he had avoided carrying the disease.

Dr. Caldwell asked whether any of the gentlemen had had any experience with reference to conveyance of scarlet fever by the cat. He referred to a case in which it seemed conclusive that the disease was so carried, and he believed from his observation and experiments on animals that the disease could be conveyed in that way, although it might not be possible to prove it absolutely.

Dr. J. C. Peters said that some time ago he published an article, in the *New York Medical Journal*, with reference to the conveying of scarlet fever by cats and dogs, and he then cited the experience of Dr. Hadden and Dr. Bates, who had seen several such cases. He had seen one case in which the suspicion that the disease was carried by a pug-dog was very well founded. Many years ago he carried measles from a child six or seven years of age, in Eighth Street, who was in the period of desquamation, to a child in Thirty-fifth Street. He had handled the hand of the child in Eighth Street and had left the house without washing his hands. On his arrival in Thirty-fifth Street he found a child suffering from symptoms which rendered it necessary for him to put his fingers into the patient's mouth, and in ten or twelve days the child had measles. He was unable to trace the disease in the second child to any other source than to the fact that he had carried the disease on his hands from Eighth Street.

Concerning the long duration of the poison of scarlet fever, he referred to four cases in one family which he attended some years ago. After the occurrence of these cases another child was born, and it was probably six or eight months old before it was brought back to the city and to the house where the scarlet fever had previously occurred. The room in which the former children had been sick had been thoroughly renovated. The only article which had not been disposed of or thoroughly disinfected was a stuffed sofa, which was put up into the upper room where the children played during bad weather. The youngest child was taken into this room and placed upon the sofa, where it pounded it after the usual fashion, and raised a dust. This child was taken with scarlet fever and died within thirty six hours.

Dr. J. E. Winters said that the questions, how early and how long the poison of scarlet fever might be infectious, were most important. He believed that during the pre-eruptive and the post-febrile periods scarlet fever was more freely conveyed than during any other period of the disease. It was not often that children were exposed to the disease during the eruptive period. He thought the disease was contagious from the very first moment that the initiative fever began, and cited two or three remarkable cases which sustained the view that it could be communicated as soon as the first symptom developed which showed the process of elimination of the poison of the disease. During the period of eruption the disease was most likely to be conveyed from the breath, exhalations from the skin, vomited matter, and all discharges, and during this time special attention should be given to the disinfection of these discharges. In the tenement-houses in New York the discharges were probably not disinfected, and he thought it was a subject which should receive the attention of the Board of Health. It had been long recognized in hospitals for contagious diseases, especially scarlet fever, that unless thorough disinfection was resorted to the disease would be carried to the healthy through the medium of clothing, etc., etc.

As to the duration of the contagium of scarlet fever, he felt that the best advice which could be given was included in that given by Watson in his lectures, namely, to "say that you do not know." It had been said recently in this city that scarlet fever was not contagious more than four or five weeks, perhaps during a shorter period of time than this. The contagious principle, however, in the post-febrile period existed especially in the scales shed from the skin, and therefore during the entire period of desquamation, no matter how long it might exist, there was a possibility that the disease might be communicated. The higher the fever the greater the irritation, congestion, and œdema of the surface, and the greater the amount of desquamation. The protection of the period of desquamation, which was largely affected by the constitution of the patient, season of the year, and the care which the patient received. Children in feeble health, greatly exhausted bodily disease, especially scrofulous and phthisical children, children suffering from catarrh of the alimentary canal, have a long period of

desquamation. Children who are neglected during the time of desquamation have a long period in which the poisonous scales are shed from the skin. If the period of desquamation extend into weeks, it will be weeks during which the child will be capable of conveying the disease, and he believed that these were points which should be taken into special consideration in studying the question of contagion. Dr. Winters also believed that otorrhœa could convey the contagion for weeks, possibly for months. He cited a case in which the patient had scarlet fever in Florida. Several months afterward the patient returned to this city. The desquamation was complete, but the child had an otorrhœa. That child was taken to the country, where it came in contact with a child that had not been previously exposed, and who contracted scarlet fever within forty-eight hours after the arrival of the child that had had the disease in Florida. The attending physician was of the opinion that there was no source of infection except that conveyed by the patient coming from the South.

Another source of contagion in scarlet fever after the febrile period was the throat. Those children with enlarged tonsils where a catarrhal condition remained for a long time after scarlet fever, he had reason to believe, could convey the disease, and therefore such children should not be allowed to sleep with other children for several months.

Dr. Peabody said it had seemed to him that a grave error had been committed with reference to the danger of conveying scarlet fever to lying-in women. He would ask if there were any facts which bore upon the following points: First, is the lying-in woman especially susceptible to scarlet fever, and, second, is it possible to convey any other disease to her except scarlet fever, such as septicæmia, after having visited a patient sick with scarlet fever? He had studied the question somewhat, and had not found a single well-defined case in which the scarlet-fever poison had been carried to the lying-in woman. He thought that the same blind authority had been followed with regard to this opinion as had been followed with regard to going from an autopsy-room.

The Chairman remarked that the lying-in woman was more susceptible to contagion of all kinds than she would be under other circumstances.

Dr. Peabody said that he had no doubt but that she was, but he would like to ask the Chairman if it was not an adherence rather to superstition to lay so much stress upon the statements to which he had referred, as had been frequently done.

The Chairman said he had had no experience which would lead him to believe that scarlet fever was conveyed more frequently to the lying-in woman than to others. He thought that scarlet fever was not readily taken by adults who had not had the disease in childhood.

With regard to the danger of physicians carrying scarlet fever to their patients, it seemed to him that Dr. Hudson's statements were rather strong. He did a general practice for many years, and was accustomed to take his own children to ride with him in the coupé, which was closed, and had never hesitated to visit patients sick with scarlet fever, perhaps two or three in the same room, and going directly to his coupé where his children were, and from there to visit other children who did not have scarlet fever; he had not taken the pains to change his clothing, or treat it in any special way, and had never had any fear of carrying the disease, nor had he known that he had ever propagated either scarlet fever or measles by neglecting to take the precautions which had been mentioned. His own experience would lead him to believe that it was a rare exception for physicians to carry these diseases from one house to another in their ordinary visits.

Dr. Andrew H. Smith had had one singular observation with reference to the period of incubation of measles, showing how a person might be exposed to the contagion and escape, and then be exposed at another time and take the disease. A young physician contracted measles. During the period of incubation he was in the house of his sister and around her children. Exactly fourteen days after he broke out with measles his sister's youngest child broke out with measles; exactly fourteen days after this child broke out with the disease the oldest child showed the eruption; and precisely fourteen days afterward a young lady who was staying in the house came down with measles. The series of cases was interesting because of the fact that the second and third persons attacked took the disease from each other, and not from those first sick with the measles.

As to the portability of measles and scarlet fever, it seemed to him that it was the duty of the profession to disabuse the public of the absurd ideas concerning their communicability which were prevalent. He then referred to the excessive fear manifested by many persons with reference to taking these diseases, carrying it even to the neglect of patients who suffered from the affections.

Dr. L. Emmett Holt referred to an article published in March last in the Glasgow *Medical Journal*, by Aikman, in which he reported an epidemic of measles in the island of Guernsey, where the disease had not prevailed for many years. Three or four thousand cases occurred, and among these there was noticed a striking immunity among lying-in women throughout the entire epidemic.

The Section then adjourned.

Correspondence.

THE INTERNATIONAL MEDICAL CONGRESS.

CONCERNING THE THREATS OF NEW CODE MEN AT COPENHAGEN — CORRESPONDENCE BETWEEN DR. A. JACOBI, OF NEW YORK, AND DR. J. V. SHOEMAKER, OF PHILADELPHIA.

110 West Thirty-fourth Street,
New York, May 3, 1885.

Dr. J. V. Shoemaker, Philadelphia.

Dear Sir: The *Medical News* of May 2d contains on p. 494 the following: "Dr. J. V. Shoemaker said new code men had made threats at Copenhagen in his presence, hence the statement that he had made was true, as men who had made these threats were now on the committee." As far as I know, the only "new code man" on the General Committee of the Ninth International Congress is myself. It is natural, therefore, that I should be anxious to know if you accuse me of having made threats. Very respectfully yours,

A. Jacobi, M.D.

Philadelphia, Pa., May 5, 1885.

Dr. A. Jacobi.

Dear Sir: The account in the *News* was not exactly as I made the remarks. As near as I can remember, the concluding sentence was, the statement that I had made was true, as the new code men were fully represented on the Congress, which was the very best evidence of their recognition by the Committee.

Yours, respectfully, J. V. Shoemaker.

New York, May 7, 1885.

Dr. J. V. Shoemaker.

Dear Sir: Beside the *Medical News*, to which I referred you in a previous note, you are reported, in The Medical Record of May 2d, to have said that "the Committee . . . yielded to the threat made by the new code men at Copenhagen, that unless they were recognized, they would use their influence to prevent the Congress from coming to the United States."

I cannot repeat, that I must request you—as I am the only "new code man" on the Committee—to explain what induced you to make the statement you are credited with, or what may have been the cause of the uniform reports in the journals.

Very respectfully yours, A. Jacobi, M.D.

PHILADELPHIA, PA., May 9, 1885.

DR. A. JACOBI.

DEAR SIR: I stated in my remarks, which have not been fully reported in any of the accounts that have appeared, the predictions made at Copenhagen, which have been verified by the present arrangement of the Congress.

Yours truly, J. V. SHOEMAKER.

110 WEST THIRTY-FOURTH STREET,
NEW YORK, May 11, 1885.

DR. J. V. SHOEMAKER.

DEAR SIR: The *Boston Medical and Surgical Journal* of May 7, 1885, p. 456, has the following sentence: "Dr. Shoemaker repeated that the new code men had made threats at Copenhagen."

The *New York Medical Journal* of May 2, 1885, p. 500, writes as follows: "Dr. John V. Shoemaker . . . alleged . . . that the new code men present" (at Copenhagen) "had openly threatened that they would prevent the acceptance of the invitation unless they received full recognition; as a consequence, they had been recognized, as was shown by the fact that they had been given some of the prominent positions with reference to the Washington meeting."

These reports agree fully with those I quoted in my previous notes, from the *Medical News* and THE MEDICAL RECORD.

Thus you will pardon me for saying that your two notes did not answer my questions concerning the language quoted.

Permit me to ask again:

1. Did you say the new code men had made threats at Copenhagen?

2. If so, what are the facts supporting such a statement?

3. If not, what was the remark you made?

Pardon me for requesting an answer, for I have to repeat again that I am the only "new code man" on the General Committee who can have been referred to.

Very respectfully yours. A. JACOBI, M.D.

PHILADELPHIA, PA., May 13, 1885.

DR. A. JACOBI.

DEAR SIR: Your letter of May 11th is before me. It affords me pleasure to assure you that in my remarks at New Orleans I said nothing that was intended to personally implicate you. You need offer no apology for your persistency, as this explanation would be due any gentleman who regards himself compromised.

I infer from your letter that a personal explanation is what you want, and I am glad of this opportunity to place in your hands such documentary evidence as will exonerate you, if you have been wrongfully accused by others.

If you want any further information for public purposes, I have but to add that it will be *forthcoming* at the *proper time* and *place*. You will agree with me that your claim upon me can only personal not all (? A. J.) affecting individuals. So let me again assure you that I shall be most happy to make any explanations that will relieve you of any censure that my remarks may have brought upon you personally.

Yours respectfully, J. V. SHOEMAKER.

May 14, 1885.

DR. J. V. SHOEMAKER.

SIR: Your note of May 13th convinces me that you mean to persist in evading a straightforward and honest answer. I asked a few direct and intelligible questions, and you refuse to give anything but circumlocution.

When you spoke in New Orleans you knew you said what was untrue. And now that you are called upon for an explanation of your conduct, you try to wriggle out of your responsibility.

You are altogether mistaken if you think—which I do not believe you do—that I need or desire any justification or exoneration at your hands. You know that what you said in New Orleans about threats being made was not true, and your letters show that you have not the courage to stand up to it. A. JACOBI, M.D.

NOTE.—A letter of Dr. Shoemaker's which arrived two or three days afterward, was returned to its writer, unopened. A. JACOBI.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 17, 1885, to May 23, 1885.

DE LOFFRE, A. A., Captain and Assistant Surgeon. Relieved from duty at Fort Sissiton, D. T., and ordered to Fort Totten, D. T. S. O. 52, Department of Dakota, May 14, 1885.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Ordered for temporary duty at Fort Omaha, Neb. S. O. 44, Department of the Platte. May 18, 1885.

MUNDAY, BENJAMIN, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Klamath, Oregon, and ordered to Fort Walla Walla, W. T. S. O. 72, Department of Colorado, May 12, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 23, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

THE MISSOURI STATE MEDICAL SOCIETY.—(Condensed from a special report to THE MEDICAL RECORD.) The annual meeting was held this year at St. Joseph, and was attended by an unusually large number of delegates. At the opening session addresses were made by the Mayor of the city and the Chairman of the Committee of Arrangements. Dr. B. F. Trader, of Sedalia, read the first paper, on "Cholera." Having once inadvertently given a large dose of carbolic acid to a woman in the stage of collapse, with the result of curing his patient, the author was led to make an extended trial of this remedy, and was greatly pleased with its effects. He regarded hypodermic medication as of especial value in this disease. Quite an animated discussion followed the reading of this paper, and a great variety of opinions was expressed both as to the nature of the disease, and as to its treatment. Dr. Stringfellow advocated the use of corrosive sublimate as a prophylactic on theoretical grounds. Dr. Prewitt thought that the stage of collapse was a condition identical with that known to the surgeon as shock. He regarded the hypodermic use of morphine and atropine as a method of treatment that promised the best results. Dr. J. C. Mulhall, of St. Louis, then read a paper on "Atrophic Nasal Catarrh." He regarded this affection as of neurotic origin, not consequent upon hypertrophic disease, and not due to syphilis. It was progressive and incurable, and the cases which were apparently cured were simply those in which the morbid

process had advanced so far that the mucous glands were completely destroyed. His plan of treatment might be summed up in the one word, "cleanliness." He employed the nasal douche, and had never seen any ear trouble resulting from it. Dr. C. H. Hughes presented a communication on "Neglected Precursory Symptoms of Brain Disease," laying especial stress upon apparently causeless changes in the disposition, habits, or ability to work. He dealt simply with the psychical, and not the physical, manifestations of cerebral disease. The paper was discussed by Drs. Catlett, Mudd, and Hanna. Dr. J. H. Thompson, of Kansas City, presented the report of the Committee on the Progress of Ophthalmology, referring especially to the use of jequirity and cocaine, to stretching of the infratrochlear nerve in the treatment of glaucoma, and to the increasing use of small probes instead of cutting instruments in stricture of the lachrymal duct. Dr. J. F. Lutz, of St. Louis, read a paper on the "Diseases and Treatment of Cicatrices," and exhibited a bone specimen showing an epitheliomatous growth which had developed in the cicatrix formed after a compound fracture. Dr. Prewitt thought that the fact of malignant disease occurring in scars and ulcers was an evidence of the primary local nature of carcinoma. Dr. J. P. Kingsley then read a paper on "Malaria in Children." He had seen malarial fever in children from a few days to a few weeks old, and he believed the poison could be taken in through the mother's milk. Distinct chills in little children are rare, and sweating is absent in infants under one year of age. Malarial cachexia develops quite early in young children, and enlargement of the spleen is more common in them than in adults. In infants the author had seen convulsions occur as the first stage of a malarial paroxysm, and in older children chorea and epilepsy seemed in some cases to be referable to the same cause. He relied chiefly upon quinine in the treatment of malaria in children, but had also used Fowler's solution, tincture of iodine, and carbolic acid, with good results. Dr. Mudd had been pleased with the results of using a pad in which about a drachm of quinine was quilted; this was dipped in alcohol or whiskey, and bound upon the epigastrium of the child. Dr. F. M. Johnson believed that children do have chills, as evidenced by coldness of the nose, fingers, toes, etc. Dr. Stringfellow was very sceptical as to the occurrence of malaria in little children, and he had entirely abandoned the use of quinine in the fevers of early childhood. He employed small doses of calomel with satisfactory results. Dr. G. C. Catlett read an interesting paper on "The Asylum Treatment of the Insane," which was referred to the Committee on Publication without discussion, owing to the lateness of the hour. The President, Dr. Middlekamp, then delivered the annual address. He advocated the elevation of the standard of medical education, and said that the profession at large was primarily responsible for the present low standard. If physicians would recommend for the study of medicine only such men as were morally and mentally fit, and would send them only to schools which imparted a thorough education, the schools would quickly raise their standard in accordance with the demand. Dr. Hanna, on behalf of the sub-Committee on Diseases of Children, then read a very interesting paper on the "General Management of Disease in Children." He advocated the giving of medicines very sparingly, careful watching, tender nursing, the removal, when possible, of sources of irritation, and special attention to nutrition. Dr. Wilson, of Salisbury, followed with a paper on "Typhoid Fever," in which he opposed the antipyretic treatment, believing that the rise of temperature was an essential feature of zymotic disease, and that any successful attempt to prevent it simply prolonged the fever and increased the danger of enteric lesions. He relied chiefly upon opium and alcohol in the treatment of the disease. The reading of this paper gave rise to a prolonged discussion, in which, though many diverse views were expressed, the general consensus of opinion was that quinine was injurious and served only to prolong the fever. The next paper was by Dr. R. M. Funkshauser, of St. Louis, who presented therein his theory of "The Determination of Sex." From a number of experiments upon animals he had been led to the belief that spermatic fluid from the right testicle will beget male offspring, and that from the left female. The ovum had little or nothing to do with the sex of the fœtus. These views were opposed by several members who took part in the discussion. Dr. Brooks, of Carthage, then read a report of a number of cases of "Injuries of the Larger Joints," giving results which he had obtained in his own practice. The election of President was now in order, and was the occasion of quite a spirited contest. Several names were put in nomination, and a decision was reached only after a number of ballots had been taken. The successful candidate was Dr. George C. Catlett, of St. Joseph. The other officers chosen were: Vice-President—Dr. C. A. Todd, of St. Louis; Secretaries—Drs. J. H. Thompson, of Kansas City, and J. C. Mulhall, of St. Louis; Treasurer—Dr. C. A. Thompson, of Jefferson City. St. Louis was decided upon as the place of the next annual meeting. On the evening before the last day's session the delegates partook of a banquet at the Pacific House. Addresses were made by the Mayor of the city, the retiring President and the President-elect, various members of the Association, and other invited guests.

Impaction of the Bowels.—Dr. W. A. McDonald, of Lynn, Mass., writes: "Dr. Fred. L. Kingsbury, of Samorov, Bulgaria, reports a case of impaction of the bowels, and asks what was the cause of death. In reply I would say that *impaction of the bowels* with improper treatment of the case on his part brought about the fatal termination to the patient. It is the duty of every intelligent and capable physician to first determine, in such cases as the one in question, as to whether the rectum is or is not impacted with fæces. If it is impacted the proper course to take before administering purgatives is to thoroughly remove by the finger or a large smooth spoon-handle, or some other such implement, the contents of the rectum, and then by tepid soapsuds injections and careful and persistent manipulations of the colon through the abdominal walls, work the hardened masses along, removing them from the rectum, as they reach there, with the finger or spoon-handle, as already stated. To administer croton-oil or any other drastic purgative in such a case as Dr. Kingsbury's, without first removing the *boulder* from the *gateway* would be bad, bad practice. The Doctor says he gave *copious rectal injections*, after giving strong purgatives; and in the same breath states that the rectum was so impacted that the water simply ran back. By this I would infer that he simply tried to give 'copious injections,' but failed entirely, because of his lack of practical judgment in treating such cases. In addition to what I have already suggested as proper treatment in cases of impaction of the bowels, I would also recommend the use of electricity to promote the peristaltic contractions by placing the negative pole in the rectum and the positive pole over the epigastrium, varying the position of the latter pole occasionally by passing it over the track of the colon."

As a Useful Prescription in Common Colds, Professor Bartholow offers the following:

℞. Codeiæ ..... gr. j.
Syrup. scillæ comp.,
Syrup. tolu .....āā f ʒ ss.
M. Sig.—A teaspoonful pro re natâ.

—*Col. and Clin. Record.*

The Crying Medical Error of the day is the mistaking nerve disease for womb disease. From this widespread delusion it has come to pass that no organ in the human body is so overtreated, and consequently so maltreated, as the womb.—*William Goodell.*

The Medical Record

Vol. 27, No. 23 NEW YORK, JUNE 6, 1885 Whole No. 761

Original Articles.

THE LIMITATIONS OF THE DIAGNOSIS OF MALARIA.[1]

By E. DARWIN HUDSON, JR., M.D.,

PROFESSOR OF DISEASES OF THE CHEST AND GENERAL MEDICINE, NEW YORK POLYCLINIC; PHYSICIAN TO BELLEVUE AND ST. ELIZABETH'S HOSPITALS.

THE diagnosis of a disease, or a conclusion as to the morbific influence which has determined a group of existing symptoms, should be reached by study of the laws and phenomena of the malady or of the materies morbi in question, as presented in typical cases. There is so much room for indefinite inference and unconfirmed theory in medicine that conservative physicians will always receive with caution, and only after careful scrutiny, all diagnoses of irregular or typical forms of disease.

This conservatism should be exercised nowhere, perhaps, with more vigor than with reference to malaria and malarial disease, since in malaria we have an unseen and impalpable agency. It is true that the discovery of the *bacillus malariæ* in marsh air in 1879, by Klebs and Crudeli, its culture and transmission by inoculation to lower animals, and the further detection by them and later observers of this bacillus in the human blood, give promise of a future possible means of exact diagnosis of malarial toxæmia.

But at present the malarial bacillus is exceptionally demonstrated in the blood of pronounced malarial cases, and by different microscopists with such discrepancies as to appearance that it cannot be included as a factor in diagnosis. Like the waxy infiltrate, which neither chemistry nor the microscope have yet detected in the blood, though its blood origin is inferred unerringly from its method of deposition and relation to visceral nutrition, so malaria, though undefined and undescribed, as an entity or potentiality, still is positively recognized by its typical manifestations as having invaded the system.

Its origin in the earth, its relation to decaying vegetation, its presumably cryptogamic nature, the laws of its dissemination by air and water are recognized; but as yet malaria itself has not been detected. The several designations *intoxication tellurique*, *malaria*, marsh miasm, however, apply to a cause of disease, which is accepted with singular unanimity by scientists, and by all classes of practitioners, and the public.

In hazarding a diagnosis of malaria, we must be guided by well-formulated rules and closely adhere to them. They must refer to evidence of exposure, the usual method of its invasion, the usual sequence of its symptoms, its progress by periods and stages, its sequelæ, and the confirmatory evidence of physical diagnosis, as to change in size and structure of the viscera. These evidences may all be present, associated or consecutively, or only in limited number characteristically grouped, or finally there may be but a single isolated symptom or sign possessing diagnostic value.

It would be undesirable to review all the features of typical malarial fever, as present in the quotidian or tertian intermittent, or in remittent fever. Suddenness of onset, rigor, subsequent fever, with an elevation of temperature disproportionate to the short period of sickness and amount of tissue waste, a speedy subsidence, with sweating, a notable relief of acute symptoms in the intermission, periodicity of recurrence, and enlargement of the spleen, are the essential features. Many others may coexist and strengthen the history of the disease. The diagnosis of typical malarial disease is thus made with unerring certainty. But when only lesser symptoms, individually or in groups, are present, and especially symptoms which may result from other causes than malaria, we have need to exercise the utmost scrutiny, and should eliminate each and every such cause before asserting the toxæmic presence of malaria. It may be stated thus: Before diagnosticating a morbific origin in an invisible, inappreciable, and inferred cause, which, if present, is manifested by its typical symptoms, we must search for other and known causes of these same symptoms, causes which, if present, are demonstrable. The exclusion of these definite causes leaves the just inference that the less demonstrable cause exists.

I would also protest against giving undue weight to the therapeutic argument. The cure of a sickness or the alleviation of its symptoms by a remedy or remedies which specifically cure malaria, does not warrant a diagnosis of malaria, when the symptoms are atypical, and when the medicine is known to be beneficial in other morbid processes, as in fever and inflammation. In most systematic treatises it has been customary to group the atypical cases of malaria under two heads: 1, Masked intermittent; 2, chronic malarial infection. The former group includes cases in which there is less danger of error or a hasty inference of malaria than in the second, since periodicity is the characteristic feature and chiefly determines the diagnosis.

A reference to numerous authors will disclose an extended list of general symptoms and local disorders, regarded, by reason of their periodic recurrence, as dependent either wholly upon malaria, or as regularly aggravated by its influence. Thus of the nervous system, malaria may cause periodically: convulsion; coma; coma-vigil; hallucination; delirium; mania; insomnia; aphasia; aphonia; hemiplegia; paraplegia; paralysis of tongue; paralysis of deglutition; anasthenia of nerves; neuralgia, trigeminal, occipital, intercostal, sciatic, lingual, cardiac, gastric, intestinal, and indeed neuroses of almost every nerve in the body. It is pretty generally conceded that trigeminal neuralgia, especially of the ophthalmic division, either periodically present or aggravated at definite intervals, is the most frequent form of the masked intermittent.

Of the diseases of the eye, malaria has been asserted to be causative, in individual cases, of amaurosis, amblyopia, nyctalopia, iritis, ophthalmia.

Periodic deafness has been noted.

Of the respiratory diseases, there are enumerated instances of asthma, pleurisy, pneumonia, hæmoptysis, phthisis directly attributable to malarial poison.

The heart rhythm, it is conceded, is often notably deranged, its force and frequency inhibited by malarial influence upon the nerve-centres. Exacerbations marked by typical periodicity, or the periodic recurrence of the disease in full, stamp as malarial many cases of indigestion, vomiting, diarrhœa, dysentery, icterus.

So, too, dermatologists have noted cases of erysipelas, purpura, roseola, urticaria, pemphigus, which have presented evidences of dependency upon malarial infection.

Renal engorgement with intermittent hæmaturia is a

[1] Read at the Section on Practice of Medicine, New York Academy of Medicine, May 19, 1885.

common feature of malaria in some parts of this country, especially in Mississippi.

Indeed, it is hardly necessary to enumerate the varied disorders to which malaria may lead, since it is recognized as a ferment vitiating the blood, provoking fever, and increasing tissue-waste. The irritation of nerves by vitiated blood, and the local hyperæmia consequent upon raised temperature and vascular excitement, will account for the widest distribution of neuralgic pains, for paresis, paralysis, and various general and limited visceral inflammations.

In each and every one of the above enumerated and all other maladies the presence of malaria, as a cause or as a complication, may be inferred: First, when other and usual causes are not apparent; second, when periodicity and other evidences of malaria, as dusky face and increased splenic area, co-exist. But without these or other recognized malarial symptoms the diagnosis is but a surmise.

I am averse to the prevailing fashion of the day, to ascribe vague symptoms—such as bodily languor, morning lassitude, persistent yawning, soreness of the muscles, bilious tinge of the skin and conjunctiva, coated tongue, eructations, torpid liver, sluggish bowels — to malaria. The diagnosis, in the last generation, of "liver disease," or "biliousness," was equally a makeshift to cover inexact knowledge, but was often much nearer the truth, since the indigestions are most frequently the cause of all the above-named symptoms.

The second group of atypical malarial disease, that of chronic malarial infection, is made to include most of the above vague symptoms. Whether symptoms are definite or indefinite, if splenic enlargement alone can be demonstrated, a diagnosis of chronic malarial toxæmia is fully justifiable; the association of fulness of the liver, of cachetic facies, bilious hue, indigestion and general innutrition, debility, and malaise further strengthens the conclusion.

But in many sections of our country, but slightly infected, as New York, these manifestations of chronic malaria are less pronounced, the spleen is questionably increased in size, the liver is unchanged. The diagnosis, then, is difficult, and demands a review not only of prominent symptoms, but of every point touching the possible presence of malaria.

What are the reasonable proofs of malarial infection?

1. The history of a residence in a malarial district, or some known exposure to malarial emanations.

Where malaria exists in a virulent form, constantly developing numerous typical intermittents and remittents, the inference is warrantable that many or most other diseases and all cases of indefinite type are influenced by the prevailing infection. Such a region was Batavia, N. Y., which, as described by Waring, was threatened with depopulation by malarial disease, though subsequently rendered healthy by efficient drainage. Certain suburbs of New York, as portions of Staten Island, the valley of the Hackensack, the Palisades, are so malarial as to develop all the pronounced evidences of chronic malaria.

In our city limits it was once customary to state that malaria was rarely engendered below Fiftieth Street. But there are evidences of the incorrectness of this statement. Isolated and grouped cases in various parts of the city point to local sources of malaria. The extensive belt of filled land which surrounds the city, with consequent extension of the sewers out through marshy land, has added a source of infection. Constant excavations—as for deep cellars, for the columns of the Elevated Railroads, for the large water-pipes—are constantly provoking malarial seizures in the workmen exposed and in the residents at the exposed points. We cannot doubt that the same influences to some slight extent leave a chronic malarial contamination. We have another possible source of danger from malaria in our water-supply. Investigation will show that the residents along the water-shed of the Croton River and in the region of the Croton Lake suffer from malaria. My attention was first called to this fact by private patients who had summered at the Croton Lake until driven home by severe chills. I believe that malaria may reach us by our water-supply. We are warranted in this opinion by data as to the Mohawk and many other valleys, to which malaria has been conveyed from its habitat to places receiving the water-shed of a malarial region, yet having no swamps or other soil of their own favorable to malaria. The cerebro-spinal fever of 1872 in this city was associated with a remarkable presence of decayed leaves and vegetation in our water.

The present season has witnessed an unusual prevalence of "winter diarrhœa," so characterized by elevation of temperature and evidences of periodicity as to warrant a malarial element. The geographical distribution of the cases in different parts of the city, and the circumstances as to habits, occupation, diet, etc., of the patients, have left but one inference, or as the most plausible inference, the water-supply. During the past year I have advised families, especially those having young children, to boil drinking-water as a means of further security against sickness, and in several instances with most notable absence of slight ailments and indefinite febrile disturbances, which had in previous seasons been present.

Maclean, in his article in Quain's "Dictionary," speaks of water from malarial coasts, taken on shipboard, as a cause of malarial fever, in persons consuming it, who had not been exposed.

The exposure of milk, in cans, to the night air, on the many valley railroads converging in New York, at the milk stations, and as peddled around our streets in the early morning air, is another possible cause of infection. For this reason, sealed cans direct from the dairy are desirable, at least for invalids and delicate children susceptible to slight malarial influences.

2. The second reason for inferring malarial toxæmia is the occurrence of a characteristic malarial seizure—an initial chilliness, chill, or rigor; sudden elevation of temperature, fever of an hour or two duration, subsidence with sweating. Or initial chill, with pronounced fever, marked by remissions, with or without local congestions with each return of fever.

These two are the typical intermittent and remittent. The latter, it is well known, ultimately becomes intermittent, as convalescence is being established. The phenomena are not materially different in method of production or in sequence in the two diseases—chill is proportionate to the shock of malarial toxæmia, the fever period represents the disturbance of tissue metamorphosis resultant from the miasm in the blood; sweating or other colliquative change, as diarrhœa or diuresis, represent an effort at elimination. In intermittent, the fever is shorter, the interval long. In remittent, the fever persists and the remission is brief, or even not obvious, but ultimately lengthens as nature, either unaided or aided by medication, completes the elimination of malaria from the system.

3. We are warranted in diagnosticating malaria, quite independently of the nature of the special symptoms, if they are clearly marked by periodicity of recurrence, or by periodicity of exacerbation.

4. A demonstrated periodicity of the temperature line, even though slight — fractional — if continued without other marked symptoms, plainly denotes malaria.

5. Changes in the size of the spleen and liver as shown by percussion and auscultatory percussion, when associated with history of malarial exposure, or former malarial seizures, lead to the inference of chronic malarial infection. But it must not be forgotten that without such history, especially if the enlargement of the liver be great, the two organs are more likely to be invaded by the waxy infiltrate. Both waxy spleen and ague cake are painless.

6. I place sixth and last the therapeutic argument.

Invariable benefit derived from the use of antiperiodics, whether derivatives of cinchona bark, salicin, eucalyptus, or arsenic, goes to confirm the diagnosis. But if no periodicity in symptoms has existed, if no enlargement of spleen is present, even though lesser symptoms suggest malaria, the cure of the case does not prove that malaria is present. Quinine not only antagonizes or neutralizes malaria in the blood, but also controls hyperæmia, inflammation, and febrile temperature. It also acts as a stimulant to the nervous system and a tonic to the mucous membrane of the stomach and intestines.

Having stated the chief diagnostic rules for determining malaria, I desire to submit a list of diseases which are constantly being confounded with malaria by many practitioners. The error is one which may threaten any physician, however expert as a diagnostician, if a case be hastily observed, or infrequently visited, or carelessly recorded.

(*a*) Phthisis will certainly rank first in diagnostic importance. The most frequent error, and one which is hardly justifiable in the case of adults, is to mistake the daily hectic of phthisis for quotidian intermittent. In this vicinity intermittent is so infrequently quotidian in the adult, as to always create scepticism as to the malarial nature of a daily chill and fever. Careful exploration of the chest will usually detect the tuberculization, the softening or cavity which create the pyrexia. In phthisis not only do patients long mislead themselves with the supposition that they are suffering from malaria, but physicians very frequently, either by oversight, or by being too willingly biassed by the patient's statements, fall into the same error. Acute miliary tuberculosis and marasmus also are occasionally, but less often, misinterpreted as forms of low continued malarial fever.

(*b*) The next frequent error, and a common one, at least in this community, is to overlook follicular tonsillitis, at least for one or two days, and mistake the sudden accession of chill, high fever, and general soreness of the muscles for an attack of acute malaria. The ultimate development of a painful throat is apt to correct the diagnosis. Follicular tonsillitis is in no true sense malarial. In endemics it is the common product of foul streets and gutters, and of sewer and house-pipe emanations; it is septic, not malarial. Individual cases are the result of catching cold, checked perspiration with associated indigestion. During the present season I have, at two different times, treated groups of eighteen and twenty cases of follicular tonsillitis in a child's day nursery; no inmate being exempt, yet no case of intermittent, or any symptom or group of symptoms characterized by periodicity, occurred either during or subsequent to these cases.

(*c*) The fact that continued fevers and the exanthemata at their outset are liable to be confounded with intermittent and remittent, all practitioners know. We are constantly compelled to exercise discretion, to defer the diagnosis until the special evidences of each disease have developed.

Typhoid will often present no typical temperature line, and remittent or malarial typhoid is inferred. But the second week will develop the typhoid spots, ochre-colored diarrhœa, and other symptoms of undoubted typhoid fever. Relapsing fever can scarcely be distinguished from remittent until the first respite, with subsequent recurrence, corrects the diagnosis. In children the passage of the time for the development of each exanthem successively clears the diagnosis.

(*d*) Inflammations of the pleura and pulmonary parenchyma may often be insidious, and at first devoid of pronounced physical signs. The diagnosis of malaria is then made, and often, in a degree, correctly, since malarial poison is a frequent cause of atypical pneumonia, either centric or localized, and is especially a cause of local dry pleurisy and pleuro-pneumonia. But if the subsequent full development of these inflammatory diseases is not marked by a continued periodicity, I should infer that the first diagnosis of malarial chill and fever was an error, to be retracted in favor of that of a non-malarial inflammation. Empyema, especially in children, and when localized, is often overlooked, and malaria diagnosticated. Physical examination. Bronchitis is not likely to be mistaken for any development of malaria, since it has so slight an initial chill, and so moderate elevation of temperature; and the substernal oppression and cough point to the true disease.

(*e*) Acute indigestion, especially in children and young adults, and those with mobile pulse and temperature will frequently produce a vascular excitement, with associated fever and even delirium, which simulate a more serious seizure, and which is often regarded as malarial. It is well in all such sudden cases to ascertain if the tongue be coated, the breath loaded, the stomach foul; if vomiting, diarrhœa, or constipation exist, and if errors of diet have been committed. A dose of oil or other quick purge is indicated, and the cure is instantaneous; whereas, resort to quinine in such cases will not particularly reduce temperature, and will indefinitely protract an otherwise speedy cure.

(*f*) But more frequent than the above-named, and perhaps than all other sources of error, indeed an everyday error in this community, and, so far as I can learn, in all sections of the country, is the habit of ascribing the manifold symptoms of chronic indigestion, of sluggish liver, and constipated bowels to malaria.

Ladies who are languid, tired, who suffer from cold extremities, vitiated appetite, and headache, are treated with quinine and its analogues, when they require only exercise, mild laxatives or enemata, regulated diet, and possibly a stomachic tonic for a brief time. Cases of lithæmia, with nervous flashes, confused head, depressed spirits, sense of fatigue, yield promptly to lactic acid, buttermilk, kumyss, or to nitro-muriatic acid, after previous long-continued and unavailing antimalarial medication.

(*g*) Anæmia, debility from overwork, nervous exhaustion, all characterized by the vague discomforts and localized pains, or neuralgia, which result from impoverished blood and deranged circulation, are too often hastily ascribed to malaria. The expenditure of more time and patience in analyzing chronic cases will obviate most of these mistakes.

(*h*) Lastly and with much emphasis, I refer to the error, largely of the past, yet still too prevalent, of misinterpreting post-partum chills and assuming their malarial nature. Most authors specify that women are more liable to malaria subsequent to confinement than before. With this assumption it has been customary until recently to interpret pronounced chills or alarming rigors, and sudden elevations of temperature in puerperal women, to malaria. I do not refer to the chills incident to the influx of the milk, inaugurating the so-called "milk fever." Even the latter seems to be materially lessened under the recently inaugurated system of obstetric antisepsis. It may be pretty safely stated that in non-malarial districts and residences, the occurrence of chills and fever in the parturient woman is not determined by malaria, but invariably by sepsis, either from membranes or clots retained in utero, or by poisonous lochia. Heroic doses of quinine, it is true, will bring down the temperature in these cases, but it will speedily rise—having been influenced by quinine as an antipyretic, not as an antiperiodic—and will remain high or fluctuate at a dangerous elevation, until thorough antiseptic douching of the uterus and vagina secures its reduction. Even in malarial regions, and in women who have previously had malarial chills, the practitioner will do well not to ignore the greater probability that he is dealing with the results of sepsis from the secundines or lochia.

In attempting to formulate the conditions which justify a diagnosis of malaria, and in detailing the many diseases which are daily mistaken for malaria, I am not to be understood as underestimating the widespread influence of

malaria in nearly all sections of the country, and the presence in every section of individuals who are suffering not only from its pronounced and typical forms, but also from varied atypical manifestations. It is too true that the error also is constantly made of treating anæmia, debility, neuralgia, and many other diseases without recognizing malaria as a possible cause. But the error is less serious in this direction, since the class of ailments so mistaken usually are not grave, nor the symptoms urgent, whereas the errors previously cited involve great hazard to life, as in the course of unrecognized phthisis or forming febrile and inflammatory diseases, or involve a protracted misconception of methods of diet and living, as in the indigestion and nervous exhaustion, or the needless sacrifice of a life as in puerperal septicæmia.

The physician who is undecided as to the merits of this argument, and strongly biassed in favor of malaria, certainly can afford to pursue the conservative course of more careful observation, and of rigid differential diagnosis, without abandoning his use of antimalarial agencies. Much good must result from a closer study of the classes of cases which have heretofore been carelessly ascribed to malaria; if still found to be truly malarial, a more precise symptomatology of malaria will be created; if not malarial, new sources of septic infection may be disclosed, or further light thrown upon the still obscure laws of assimilation and excretion.

CHLOROFORM AND THE FIFTH PAIR OF NERVES.

By G. W. WELD, M.D., D.D.S.,

NEW YORK.

Under the head of "Current News and Opinion" in the March issue of the *Independent Practitioner*,[1] there appeared a short notice relating to "Chloroform and the Fifth Pair of Nerves." The article in question briefly referred to W. E. Buck, Physician to the Leicester Infirmary, whom it would appear had stated in the London *Lancet* that "if a patient be not thoroughly under the influence of chloroform, any irritation of the fifth nerve will produce slowing of the heart's action and final stoppage through the pneumogastric nerves. He thinks this may account for many deaths in dentists' chairs, and advises that in any operation involving the fifth nerve, the anæsthesia should be pushed until the patient is completely under its influence."

This article is not only somewhat meagre in its details, imparting but little information regarding the shock which may occur during chloroform administration, but in some respects is calculated to mislead if at the same time some other points be not considered. And although I may not add anything new to what is already known regarding the influence which the fifth pair of nerves may have in connection therewith, it is, nevertheless, in relation to these points that I wish particularly to invite your attention this evening.[2]

That chloroform, when employed, should be administered until the patient is completely under its influence, *i.e.*, oblivious to pain, is self-evident and requires no comment. Under some peculiar morbid conditions it is perhaps true that incomplete anæsthesia is a condition of danger. Bartholow[3] refers to this and says that "numerous accidents have occurred from the use of anæsthetics for trivial operations—notably for extraction of teeth—in which but a partial degree of insensibility is induced. In such cases, the heart, enfeebled by chloroform narcosis, is suddenly paralyzed by the reflex action proceeding from the peripheral injury. The district of tissue supplied by the fifth nerve is an especially dangerous region, owing doubtless to the intimate connection of the nucleus of the fifth with the nucleus of the pneumogastric nerve. By far the largest number of fatal cases have resulted from a neglect of this rule. It is never safe," continues this writer, "to proceed in a surgical operation with anæsthetics, unless complete insensibility has been produced." But Trousseau and Pideux have attributed the number of cases of fatal chloroform narcosis, which have occurred in England, to the fact that "the just mentioned rule is adhered to by English surgeons." These words are as follows: "En Angleterre, les chirurgiens portent l'éthérization jusqu'à l'abolition de toutes les facultés animales, jusqu'au commencement de la période d'éthérisme organique. Plus prudents sous ce rapport que leurs confrères de la Grande-Bretagne, les chirurgiens français ont l'habitude de s'arrêter dès que la sensibilité aux excitations de la peau est abolie et que la résolution musculaire commence. Cette prudence explique comment les chirurgiens français ont éprouvé moins d'accidents graves et compté moins de morts subites" (vol. ii., p. 322).

But the impression which is likely to be conveyed in the article referring to Dr. Buck is that by pushing the chloroform until the patient is completely under its influence the chances of heart-failure may be avoided.

The fact is that chloroform, and especially if its administration be pushed, sometimes results in a fatal termination, irrespective of any irritation which may be conveyed to the pneumogastric centres through the fifth pair of nerves. Heart-failure has taken place during chloroform administration prior to the surgical operation, or the extraction of a tooth, and consequently before either the fifth pair of nerves or the pneumogastric centres, so far as the surgical shock is concerned in the matter, had become involved. Moreover fatal results from chloroform narcosis are more frequently due to cerebral anæmia induced by the upright position of the patient, who sits or reclines in the dental chair. Hence a position as near horizontal as possible is always advised whenever chloroform is administered.

It is apparent, therefore, that although the chloroform be pushed, the chances of cerebral anæmia and fatal syncope occurring during its administration still remain.

In connection with the fifth pair of nerves, and the shock occurring under chloroform administrations, the views of Bruton are worthy of consideration.

Bruton states that the blood, when it reaches the veins, is useless for nutrition of the tissues, as we see in the corpse, when the whole of the blood in the body is contained in the veins, the arteries being empty: only so long as it is in the arteries, can it maintain the vitality of the tissues. The blood is kept in the arteries, 1. By fresh supplies being pumped out of the venous system into the arterial by the heart. 2. By the contraction of the arterioles, which prevent it from running back too quickly into the veins.

When a tooth is drawn without chloroform, the irritation is carried by the fifth nerve to the nerve-centres; it irritates the vagus roots, and also the vaso-motor centre. The irritation of the vagus may depress or arrest the heart's action, so that no blood is sent into the arterial system for several seconds; but this is counterbalanced by the irritation of the vaso-motor centre, which causes contraction of the arterioles, and thus correspondingly diminishes the outflow. In a person thoroughly under the influence of chloroform, both nerve-centres have their reflex sensibility abolished, and so the irritation has no effect on either, but with partial anæsthesia (and this is doubtless the idea Dr. Buck intended to convey), the vaso-motor centre may be rendered insensible before the vagus centre, and consequently, when the irritation is applied to the fifth nerve, the vagus centre only is excited, the heart is depressed or stopped, and the inflow of blood into the arterial system is diminished or arrested, while there is no contraction of the arterioles, and therefore no corresponding diminution of the outflow. The arterial system therefore becomes more or less empty, *i.e.*, it approaches more or less to the condition of death, and fatal syncope may result.

[1] A monthly journal devoted to dental and oral science.
[2] Read before the First District Dental Society, State of New York.
[3] Bartholow, Robert: Materia Medica, p. 362. Philadelphia, 1881.

With nitrous oxide gas, however, by which the blood in the arteries is brought into venous condition, and thus acts as a stimulus to the vaso-motor centre, the danger from syncope is reduced to a minimum.

Thus we find that during the administration of chloroform for dental operations there are numbers of factors which tend to produce a failure in the heart's action.

1. A depression of the functions of the heart by chloroform narcosis, *per se;* in other words, when the paralyzation of the cardiac ganglia is due entirely to the effects of the chloroform.

2. The upright position of the patient which induces central anæmia.

3. The supposed reflex action of the pneumogastric nerve upon the heart through the irritation of the fifth pair of nerves.

These causes may of course act either separately or simultaneously, but in either case the heart's action is depressed or completely arrested. The sudden deaths which sometimes take place at the beginning of the inhalation of chloroform have been accounted for on the theory that the cardiac ganglia are in an abnormal state of susceptibility. Whether this supposition be correct or not we cannot say. We only know that there appear to be certain morbid conditions which tend to syncope. These conditions are found in alcoholic subjects, in persons who have sustained a severe shock from an injury, or are afflicted with a fatty heart; and it has also been observed that children and women (especially those in labor) are better subjects than adults and men.

It would appear from what has been said that ether or nitrous oxide gas should be used in preference to chloroform in all dental or surgical operations. In fact, it is maintained by a large majority of observers at the present day that only in extremely hot climates and in expeditions where ether, on account of its bulk, cannot be carried, is its administration fully justifiable. Statistics show about one death occurring in every three or four thousand cases—a condition of things which, if the statistics are of any value, certainly imposes an immense responsibility on the administrator. But chloroform has been used quite extensively in England, and is now used by many of the English surgeons in preference to ether.

In this country, as well as in Germany and Italy, it is used but little in general surgery. It has, however, been employed to a small extent in some of the wards of Bellevue Hospital, and, so far as known, without fatal results. It is, however, almost universally used as an anæsthetic in obstetrical cases. Dr. Alexander B. Mott, of this city, may be considered the progenitor of chloroform narcosis in this country, he being the first to administer it on this side of the Atlantic. This occurred in 1849, when it was administered for the removal of a cancer from a woman's breast, the operation being performed by Dr. Mott's father. Singular to relate, although the cancer has returned and another similar operation been performed, this woman is still alive, and, so far as known, free from the disease.

If it were possible to remove all danger from cerebral anæmia and heart depression, chloroform would doubtless be the most agreeable if not the best of all anæsthetics for capital operations. It has many advantages over ether. It produces less emotional excitement. It is as much quieter in effect than ether, as ether is than alcohol. Then the unpleasant after-effects of ether are entirely absent, the patient coming out of a state of unconsciousness apparently like sleep.

In view of these facts, it is important to ascertain, if possible, when it is found necessary to administer chloroform, the best means to employ to prevent the shock or depression which the heart appears to sustain, to a greater or less extent, whenever it is administered, and especially so if the heart be depressed by any irritation conveyed to the vagus centre on account of any peripheral injury.

Dr. Alexander B. Mott, of this city, has been in the habit, during the past thirty years, of using chloroform to a greater or less extent in his practice, and up to this date has had no fatal results. He attributes this to the careful manner of administration and the prompt and efficient remedies employed to resuscitate the patients when it is observed that their breathing is impaired or that they appear to be in danger of heart-failure or cerebral anæmia. But with him this seldom occurs, a circumstance which may reasonably be attributed to the precautionary measures taken to prevent such an occurrence before the inhalation; for he is in the habit of giving to his patients before each surgical operation a moderately large dose of whiskey or brandy and furthermore is prepared to administer it subcutaneously if necessary.

It must be considered somewhat doubtful whether the many deaths which have occurred in dentists' chairs from the effects of chloroform can be reasonably ascribed to any condition of incomplete insensibility. What seems more probable, in the light of modern investigation, is that the slowing and final stoppage of the heart is induced alone by the effects of the chloroform and the upright position of the patient rather than to any reflex action of the pneumogastric nerve upon the heart.

It is very likely that in many cases of heart depression and failure the result would have been entirely different had the above precautionary measures been taken; and in many other cases where heart-failure occurred the patients would have survived had prompt and intelligent efforts been made to resuscitate them. It is thus apparent that the present statistics relating to the number of deaths due to the administration of chloroform are of little or no value.

A number of expedients have been proposed to prevent the heart depression coincident with chloroform narcosis, but for various reasons, principally because ether is a cardiac stimulant and in consequence comparatively free from danger, no reliable formula has been proposed or at least accepted by the medical profession.

As above stated it has been suggested to give the patients a dose of whiskey or brandy before the inhalation has begun. But it is apparent from what has already been said that for one class of patients, viz., those with an alcoholic history, this remedy alone must prove uncertain and unreliable in its effects.

Nussbaum, a celebrated German surgeon, proposed to administer a subcutaneous injection of morphia. It has also been proposed to mix a small quantity of the nitrite of amyl with chloroform at the time it is given.

Sulphuric ether in conjunction with chloroform (mixed vapors) has often been administered in the same manner and with the same purpose in view.

It is a well-known fact that ether, when administered internally, is a cardiac stimulant. Thus it has been observed that in sudden and dangerous forms of syncope ether, or Hoffmann's anodyne, given internally, has had the effect to arouse a flagging heart and so prolong life.

When ether is used as an anæsthetic the heart is supposed to be the last organ affected; and if a patient dies during its administration the fatal result may be attributed to asphyxia or paralysis of the respiratory muscles. It is probably due, as just stated, to the stimulating effect which ether has upon the heart's action, that it is generally administered in a great majority of operations pertaining both to surgery and vivisection. But deaths have occurred from the effects of the administration of chloroform and ether combined, which fact tends to show that ether when mixed with chloroform is not, as an antidote, powerful enough to prevent or arrest the depressing influence which chloroform seems sometimes to hold over the heart's action. There is one other point to be considered in this connection, viz., that when chloroform is properly administered it is inhaled by the patient under a napkin and adulterated with at least ninety-five per cent. of air.

Formerly when chloroform and ether were administered together the proportions were equal parts. At the

present time, however, it is customary to use three-fourths ether and one-fourth chloroform.

The element of danger, which is coincident with the administration of chloroform and ether combined, lies in the fact that the methods prescribed for the proper administration and adulteration of the chloroform are not strictly observed. In other words, the mixture is administered by a cone as ether is administered, and so the patient receives more chloroform than if properly administered by itself.

It is obvious that whatever drugs or combination of drugs which have a tendency to paralyze the pneumogastric nerve, or remove the restraint which this nerve has over the heart, thus increasing the heart's action, or whatever agents have a tendency to stimulate the vaso-motor system, thus contracting the arterioles, must serve to produce an antidotal effect, and correspondingly diminish the chances of a fatal syncope occurring during the inhalation of chloroform.

It is true that physiological chemistry has not as yet given us any absolute antidote for the depressing effects produced by chloroform, but clinical medicine teaches us that by the administration of morphia and atropia combined we can to a great extent abolish reflex irritability, increase the power and number of beats of the heart, and maintain the elasticity and contraction of the arteries.

Bartholow says that "the subcutaneous use of atropia before the administration of chloroform lessens the dangers of paralysis of the heart and of respiration."

If from a physiological standpoint the theory of nerve inhibition be questioned, it must, nevertheless, be admitted that, so far as the heart is concerned, the use of atropia in conjunction with the administration of chloroform is inclined to ward off at least any influence which tends to depress or arrest its action. This is precisely what is required when chloroform is administered, or when, from whatever cause, the pneumogastric nerve is irritated. But beside the tendency which atropia has to increase the number of heart-beats or ward off any influence which tends to stop the action of the heart, it stimulates the vaso-motor centres and, it is said, "produces a contraction of the muscular fibres between the elastic layers of the arteries, and also of the external muscular layers of the capillaries."

When the nerves which preside over the functions of the arterial contractility are paralyzed, there is in consequence a stagnation of the blood-current, a condition which necessarily devolves more duty upon the heart. In fact, the heart is called upon to force a stream of blood through a series of paralyzed vessels, instead of vessels endowed with life and contractility, and which, as already intimated, afford assistance in circulating the blood.

Morphia adds to the efficacy of atropia, inasmuch as morphia in small doses is a cardiac stimulant.

Atropia and morphia combined have recently been suggested as a remedy for cholera,[1] on the theory that "cholera dejections and vomiting are due to a paralysis of the vaso-motor system, and that the serum of the blood transudes the mucous membrane of the stomach and the intestinal tract in consequence of these meeting with the least resistance, and that, if proper medicaments and restoratives can be administered to keep up the heart's action and the respiratory functions, the patient might survive what otherwise would be a fatal attack."

In connection with the treatment of cholera, and the effect of these two drugs combined on the heart and blood-vessels when administered hypodermically, this writer further observes that "atropia dries up the mucous membranes from the fauces to the rectum. Whether it be in consequence of its control of the inhibitory nerves of the heart, or a tonic spasm of contraction of the muscular layers of the blood-vessels, I cannot say, but that it is a dryer of mucous membranes there is abundant evidence to show. Furthermore, we know that morphine controls spasm, that it subdues pain, that it promotes quiescence, and that it has a tendency to keep the blood-vessels, and more especially those of the spinal cord, in a distended state, thereby, for the time being, maintaining the spinal cord in a state of vascular plenitude, which stimulates to proper functioning."

But what is equally important in this connection is that, after the administration of morphine, reflex action seems to be less pronounced. Again, the hypodermic administration of these two drugs combined, before the inhalation of the chloroform has begun, not only increases their physiological and antidotal effect by preventing or arresting the depressing influence on the heart's action, but the disagreeable features of both, as observed when employed by themselves, are materially lessened.

With a view of ascertaining just how far the reflex action of the pneumogastric nerve affects the heart through the irritation of a sensory nerve, the writer has recently experimented on animals with the following results: In a sheep (which had been chloroformed), after the heart had been carefully exposed, five teeth were extracted under various stages of chloroform narcosis, without producing any visible effect in the frequency of the cardiac pulsations. But a subcutaneous injection of morphine and atropine had a marked effect upon the heart's action, the number of heart-beats being perceptibly increased, and a more forcible impulse of the ventricular systole indicated.

This experiment was repeated on a dog (four teeth being extracted), with almost similar results.

So far as it is possible to judge from the experiments just alluded to, there seems to be no good reason for believing that a reflex action of the pneumogastric nerve upon the heart, through the irritation of a sensory nerve, at least the fifth pair of nerves, ever takes place during the administration of chloroform.

The special point to be noted is that, in a great majority of instances, fatal results from chloroform inhalation may be attributed to cerebral anæmia, and some fault in the administration, rather than the effects produced by giving less than the usual quantity of chloroform, or producing incomplete insensibility. Whether morphine and atropine combined, and employed subcutaneously, will prove to be an effectual antidote for the paralyzing effects induced by chloroform, time and experience alone can determine. One point, however, seems to be clearly settled, viz., that whatever the cause of fatal syncope during chloroform narcosis, the remedies most likely to prove of any value must embrace those remedies which are calculated to ward off an attack of heart-failure, rather than those remedies which are generally adopted for resuscitation, after an attack.

This is made apparent by the fact that many deaths occur suddenly, and, consequently, the agents which strengthen the cardiac and respiratory functions are applied when it is too late, and, of course, prove to be useless.

Dr. Johnson on Microbes.—All anticipation of future knowledge, and suggestions which those who come after find to be correct, have a peculiar kind of interest and are worth noting, even though the scientific basis on which they are founded may be questionable. There is an observation of Samuel Johnson's on the subject of dysentery which fairly illustrates this. In a letter to Mrs. Thrale, dated November 12, 1781, he says: "If Mr. —— will drink a great deal of water the acrimony that corrodes his bowels will be diluted, if the cause be only acrimony; but I suspect dysenteries to be produced by animalculæ, which I know not how to kill." Johnson used the word "animalculæ;" a modern writer would say "microbes."

TRAUMATIC GASTRIC FISTULA OPENING INTO THE PANCREATIC DUCT, RESULTING IN DEATH AFTER FORTY YEARS.

By E. F. BRUSH, M.D.,

MT. VERNON, N. Y.

In July, 1881, Dr. Horton, of Morrisania, sent to me for some kumyss for a patient of his who was suffering from an uncontrollable vomiting, due to some obscure disease. The kumyss was retained and the patient continued to consume five bottles daily for seven days, when the vomiting again took place, and kumyss as well as everything else was rejected. On July 15th, with Dr. Horton's permission and at the patient's request, I took the case in charge. On my first visit I found the patient, who was sixty-three years of age, tall, gaunt, with all his teeth gone, and his false teeth removed, giving the face a greatly sunken appearance. He was in bed, answered questions very feebly, had just ceased vomiting when I arrived. The temperature was 97°, pulse weak and thready, bowels normal, and tongue clean. From his wife I got the following history: In the year 1842, after eating a hearty dinner, he had attempted to lift a very heavy stone; he felt something tear in the stomachal region which he compared to the tearing of calico. He immediately fell, did not lose consciousness, but expected instant death. There was no pain immediately following this occurrence; his feelings were of a nature which he could not describe, one of the most marked being a painful anxiety to move cautiously. Three months after the occurrence he was married, and about this time consulted a physician in Boston, who pronounced the injury a diaphragmatic hernia. A year after the accident he began to experience pain in the right hypochondriac region; the pain was not severe, but very depressing. At that time he was a music teacher and was able to practise his vocation while suffering pain. This pain became periodic, occurring every three or four weeks. During the next five years he changed his occupation frequently: for one year he manufactured shoes, then became the leader of a brass band and a choir-singer, and afterward engaged in the manufacture of pianos, continuing this business till the time of his death. For three years the pain was of the same character, after which it became more intense and frequent, and about this time was accompanied with vomiting without nausea. He said he learned to vomit, thinking the act would relieve the pain. About a year later the vomiting became uncontrollable, and always followed the pain, without, however, usually giving relief. He called in at this period a homœopathic physician, who diagnosed cancer of the pylorus. He received no amelioration, but his condition remained unchanged till about ten years before his death. About this time he had an ecstatic spasm lasting about half an hour; on recovering, he stated that during the attack he thought he was dying, and would have liked to remain in that condition forever. After this occurrence he fainted frequently while suffering pain, but never had a recurrence of the ecstasy. Henceforward to his death he was always hungry and thirsty. His teeth began to decay and trouble him, and they were all removed except the stomach teeth. Two years before his death, he had a severe attack of intermittent fever which responded to treatment in a few days. While lying sick with the fever, he fancied the stomach teeth caused the whole trouble, and while still very weak from the intermittent trouble, and hardly able to walk, he arose one morning and, without saying anything to the family, had the teeth —which were sound—removed. After this he became hysterical, querulous, and constantly complaining, but insisted on working when not completely prostrated by pain and vomiting. He was convinced that his case had never been correctly diagnosed. For this reason, a few months after the attack of intermittent fever, he went to one of the large New York City hospitals for treatment. He stated that the entire medical staff examined him, but did not communicate to him their conclusions, notwithstanding his earnest requests. He overheard the order that he should be treated hypodermically with morphine and atropia. As he had always objected positively to the use of morphine, having a terrible dread of the morphine habit, he took the first opportunity after the physicians had left his ward to dress himself and quit the institution, returning home much to the astonishment of the family.

Such was the history of the patient when I paid my first visit, on July 15, 1881. All the known remedies had been used and failed, after some had afforded temporary relief. Some weeks before I saw him the pain and vomiting had occurred every three or four days, but ceased for the space of fifteen days while subsisting on kumyss. There was no other article of food or drink which made any difference in the intensity or frequency of the pain or vomiting. He would sometimes eat a hearty meal of corned beef and cabbage, or baked beans, and suffer no inconvience, and again, while subsisting on the lightest diet, would suffer terribly. A few months before I first saw him he drove to City Island; on the way from his home in Tremont he was attacked with vomiting and excruciating pain, being obliged to get out of the buggy and roll in the grass, crying out in agony. The intensity of the attack subsided in about an hour; still suffering somewhat from pain he continued his journey; in a fit of desperation he went to a restaurant, ordered baked clams for two, and, as his wife did not like clams, he ate the entire lot himself, drinking also two bottles of lager beer. From this he suffered no inconvenience whatever. These last facts he related to me himself with his feeble, querulous voice. On attempting to prescribe for him, every remedy I suggested he objected to, as having been tried in vain. I finally decided to apply a mustard plaster on the epigastrium, and after some redness was produced, the reddened area to be rubbed with chloroform. This afforded him some relief from the pain. I directed him to eat a hearty meal of beefsteak, baked potatoes, bread, butter, and ale, and if vomiting occurred to save the rejected matter, likewise the fæces and urine voided during the next twenty-four hours. When I visited him the following day, I found that vomiting had taken place about eight hours after the hearty meal, which he said he enjoyed very much. The vomited matter, about two quarts, was thoroughly digested, not a single fibre of the meat being visible to the naked eye; there was no odor to it whatever. In character it was a thick chyly-looking mass, floating on a whey-like fluid. Under the microscope there were seen numerous pus-globules, free fat, disintegrated meat-fibre, and starch-granules. The fæces also, on examination, exhibited an abundance of free fat. No other abnormality was detected. The urine, with the exception of an excess of phosphates, was normal. After this examination I made a diagnosis of *pancreatic abscess*, with a sinus leading into the stomach, and I reasoned that this abscess was stimulated by a full stomach pressing on it, and when the pyogenic sac became full it emptied itself into the stomach and caused the vomiting, while a distended sac in this region might account for the pain. Therefore I directed the patient to take little food at a time; an ordinary slice of bread and butter, half a teacupful of oatmeal gruel, or any of the lighter nutritious soups which he wished, every two hours, and to avoid meat or other fleshy foods. He followed the directions for some time with good results, but the craving for a satisfying drink and a stomachful of food was more than he could resist, and he reverted to his old habits. I stopped my regular visits and only saw him occasionally. He would come into my office at times, and tell me all about his trouble over and over and over again, and would ask me if I still adhered to my diagnosis. When I assured him that I did, he seemed pleased, and expressed the hope that I would at some time think of some way to relieve him. He would add that he also had made a diagnosis of his case,

and, like myself, he still adhered to it; his opinion was that wind in the bowels caused all the trouble.

On July 3, 1882, he came to me the very picture of misery: he threw himself on the lounge and begged me for pity's sake to do something to relieve his pain. I gave him one drachm of chloroform in a little water by the mouth; this relieved the pain a little, but caused a severe burning in the stomach. I helped him into his carriage and told him to diet himself again as I had directed the previous summer. Two days later he sent for me; I found him seated in the veranda groaning with pain; his teeth were removed and he presented the appearance of a dying man; his voice was almost inaudible, pulse, 50, and very weak; temperature, 97⅗°. I had him put to bed and directed that he receive no food whatever by the mouth, except a little kumyss to quench the thirst of which he was complaining. I gave him immediately an enema composed of one raw egg, one pint of beef solution, and a tablespoonful of brandy. He objected strongly to the injection, saying the idea was very repulsive to him. I ordered him to have an enema given every six hours, night and day, composed as above. This treatment was continued for fourteen days, during which time vomiting took place once on the fifth day, but without pain. The vomited matter consisted of green viscid mucus and pus. At the end of fourteen days, owing to his earnest solicitation, he was allowed to sit up, and in lieu of the enemata, which continued to be repulsive to him, a small porterhouse steak with boiled rice was given. This he enjoyed very much. After twelve hours the pain returned with great intensity, but there was no vomiting. I proposed the use of actual cautery over the seat of pain, but he objected so pitifully that we abstained, and used in its place mustard and chloroform, as we had done a year ago. Toward evening the pain subsided sufficiently to enable him to sleep; about midnight he aroused the family with piercing screams; he asserted that he was dying, but this had occurred so often before that the family did not enter into his convictions. Very early in the morning they sent for me. The moment I saw him I was convinced that he was actually dying, and I thus stated to the family. Dr. Campbell was sent for as consultant, and together we employed all the known means to stimulate the absent pulse, warm the cold extremities, but he failed to rally and died very quietly at 11 A.M.

After much difficulty, and the body lying in the room where death took place, without ice for two days, we finally got permission to hold an autopsy, providing we did not take away any part of the remains. Dr. Horton was invited by the family to be present at the autopsy, but was unable to come. The autopsy was performed by Dr. Campbell and myself.

Autopsy: Rigor mortis well marked; abdomen distended (with gas), below the umbilicus very much discolored; the peritoneum dull vermilion color, very much thickened, and the entire posterior portions covered with a thick firm plastic exudation; the entire intestinal tract dark red; the omentum bound down firmly to the epigastric region; the veins of the lesser omentum enlarged and distended with blood; the stomach reddened and completely bound to the peritoneum posteriorly; the spleen firmly bound to it at the greater curvature. On opening the stomach there was discovered a fistulous opening at the posterior part of the pyloric end, about four inches from the pylorus. Passing the finger through this opening, it led into the much enlarged pancreatic duct; the pylorus was completely closed, but there was no evidence of cicatrices or adventitious disease, it was simply closed tightly and would not admit the passage of a probe. The stomach was covered with ash-colored catarrhal mucus; the pancreas was bound firmly to the stomach, and was honeycombed with numerous passages where the substance seems to have sloughed out, leaving simply the envelope; this condition subsisted in about four-fifths of the gland, one-fifth of the length at the tail end still retaining its glandular form, but much reddened or almost black. It was impossible to tell whether some of the contents of the stomach had fallen into the abdominal cavity, as the undertaker, who stood by, had thrown into the cavity some disinfecting fluid, the odor being so overpoweringly offensive, and as we had, likewise, unintentionally torn the pancreas from its adhesion to the stomach. The pancreatic duct was very much enlarged, the finger easily passing through it into the duodenum. The gall-bladder was enormously distended with black bile; the liver a black-blue color and soft; the kidneys were congested without other evidence of disease.

MENTAL CONTAGION IN INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

In the October number of the *Alienist and Neurologist* I presented the results of some studies of this subject which have attracted much attention, and were undoubtedly the first effort to explain on a scientific basis the phenomena of the spread of inebriety by mental contact and personal influence.

It is apparent from the large number of letters received from others, with notes of cases and opinions confirming the conclusions reached, that the subject has been suggested to many thoughtful men of the profession before, and my paper simply organized and grouped the facts within the observation and experience of others. I propose in this note to present some additional facts and conclusions for the purpose of stimulating further inquiry in this most fascinating field of clinical psychology.

In every circle of life examples may be found of one mind dominating over another, projecting its motives, impulses, and general line of conduct, until one is a copy or imitator of the other. Among students of medical colleges there will always be examples where the conduct, manner, and forms of expression, and many marked personalities of the professors are reproduced in the students—particularly in the private students of physicians who have strong individualities. This mental contagion, or projection of thought, conduct, and motive from one to another, is more or less permanent, and where the medical teacher is known to the observer the infected student can be distinguished long after, although far removed from the source of contagion. The same thing may be studied among clergymen of large personal influence. The thoughts and reasons of a large part of the congregation are but the reflection of the clergyman's personal views. Often peculiar ideas have an undisputed existence in his circle that come from this literal mental contagion.

The delusions of the insane are often projected from one to another, and many instances are on record of entire families, otherwise sane, who are infected with the delusion of some member who is insane.

Among the sane in every-day life, how often it is possible to trace the growth of error to a mental contagion from some strong impulsive brain-power that domineers and projects itself on others. As in the contagion of small-pox, yellow fever, or cholera, favoring conditions of soil must exist for the reception, nurture, and growth of these mental contagions. The one who is the source of contagion must have some degree of emphatic nerve-force, which infects the other, who may be wanting in this, and possess some unstable and uncertain brain organism.

The early history of many cases of inebriety afford striking examples of mental contagion. The victim frequents bad company, and is influenced by inebriates, strangely, and to his great disadvantage. To call it a vice implies the exploded dogma of free-will, which is most effectually contradicted in experience, and the very few cases which are ever able to use the will to recover.

To say that this is mental contagion indicates the operation of both physiological and psychological laws, in accord with the order of nature, and in the province of science to reveal and remedy. Any careful study of a number of cases of inebriety will show that the causation came direct through the influence and contagion of another. Men previously temperate are as positively infected by the mental contagion of an inebriate as they would be from the germ of small-pox. Without doubt those who are infected from this contagion have some peculiar susceptible nerve organization, either inherited or acquired, and may be in many cases lacking in vigor or health. Hence these forces of mind over mind are more potent and find a ready soil for their growth and development.

A group of inebriates who often cause inebriety in others may be termed the impulsive irregular inebriates—persons whose drinking varies from great extremes at times to a regular moderate use daily, who may abstain for a time and appear to have more or less control over themselves, and are noted for their positive, emotional nature, and large domineering egotism, with emphatic manners. These men are found in politics and centres of power, and are frequently wealthy, and often occupy important positions as professional men and leaders. Often they are full of delusions and on the borders of mania when using alcohol, showing great brain and muscular activity. They are the heroes of apparent power, who compel admiration and adoration in the bar-room, at the club, and dinner-party.

Such men always gather round them a class of less positive minds, who are attracted at first by curiosity or some selfish interest, and sooner or later become copies and reflexes. These contagious inebriates are frequently apparent types of health, and ambitious active men of the world, but when closely studied exhibit manias of expensive, extravagant nature that are repressed by a very slight current of events. As brokers or merchants they are centres of every new movement, with boundless confidence and hope; as professional men they are agitators and innovators; as politicians they are working on new lines and by new methods. Such men have a short career, and disappear either in hospitals as chronic cases, or from death by intercurrent disease. The class of cases who are made inebriates by the contagion of this form of inebriety are equally distinct. They represent the ambitious poor, and the wealthy idler of society, often men of some genius and character, but always of weak emotional natures. As poor ambitious boys and men, their ideals of wealth and power are changeable and guided by no fixed conceptions of the means of attaining these ends. Hence they are attracted by every current of influence which seems to promise this object. Possessing unstable nerve organizations they become followers and imitators of every human embodiment of power and energy which gives any promise of changing their condition and increasing their happiness. As wealthy idlers they are attracted by the dash and stir of the surroundings of these contagious inebriates, and, like others, are soon imitators or followers. Imbibing all their delusions with the vague notions of increased pleasure and happiness, they are devotees of the most abject character.

The following are some cases of this class: A—— was a manufacturer, who owned a valuable patent, and was supposed to be a man of great prospective wealth and influence. He was an impulsive inebriate, acting with feverish delusive energy. For years he was the centre of a large circle who all became inebriates from the mental contagion of his conduct and personal influence.

B—— was a physician, and inebriate, with emphatic manners and strong emotions, who moved into a quiet New England village. He very soon took a leading place, and drew around him a class of followers who all became inebriates, following his manners and conduct with singular fidelity.

These are mere outlines of cases that are not uncommon, and are clear when explained as examples of mental contagion, examples of diseased states and impulses communicated to another, finding suitable soil, and growing rapidly to maturity. The second class of cases who are sources of contagion and infect a certain number of cases about them with a similar disease are the regular and so-called moderate drinkers—persons who from some peculiar constitutional resisting power are able for a long time to use alcohol regularly, producing in themselves a mild exhilarating effect without going further, and generally able to conceal all excessive use and continue about the same apparently for years. They are the ideal drinkers who are held up as examples in many ways in every community.

Often they occupy places of wealth and power and influence, and are emphatic in denouncing inebriety in others, and generally condemn temperance efforts. They are the champions of the moderate use of spirits, and appear at club-houses, dinners, and on all social occasions, drinking moderately, and often exhibiting intellectual brilliancy and power supposed to come from alcohol. Studied closely they are seen to be as clearly inebriates as any other class, only the delusions of the brain and organic degenerations are masked and concealed.

The delusions of health and strength are held tenaciously and urged with emphatic earnestness, forcing conviction, in less observant minds, that it is a reality. As leaders of society they are noted as using wine and spirits freely, and yet never appear to be intoxicated. These men scatter a positive contagion by their examples and arguments. They seem unmistakable examples of the value of alcohol in moderate doses, and the possibility of attaining this end in all cases. They infect the previously temperate, overworked business or professional men, who adopt their ways of living and at once become inebriates. The contagion of their inebriety makes inebriates of the physically weak, and those who are living irregular lives and suffering from neurotic troubles of various kinds; those who are ambitious to be thought strong and to win the favor of these men, and drink as they do by the contagion of example. They infect a class of men who have weak, unstable judgments, who turn in any direction to follow any line of conduct that promises better conditions. Such men cannot be temperate in the company of moderate drinkers, and they cannot drink moderately, hence are inebriates very soon. The mental contagion appeals to the reason and is enforced by the power of example, and the more prominent the man the more positive his contagious influence. These two classes occupy a very prominent position in all large business centres, and their influence in actually building up and producing inebriates is a positive demonstrable factor that can be seen and understood.

The following are examples:

a. A popular clergyman became a moderate drinker, and defended his position with a great show of reason and earnestness. His example and specious reasoning drew into his circle a large number of persons who eventually became inebriates—persons who became affected with his conduct and teachings, and could not stop where he did. His conduct broke up the church organization after a time.

b. A lawyer and moderate drinker, a man of much personal magnetism, founded a literary club and became a leader; in a short time this club changed and became a drinking resort. A large number of the members became inebriates, clearly traceable to the contagion of this lawyer.

These cases are also quite common, and are clearly instances of psychological laws and their operations which exist all about us and are unobserved at present.

Another group are sources of mental contagion quite often seen. They are the inebriates who grow out of personal intimacies of like character and organization

—persons who form attachments, adopt the views and motions of others, imbibing all their delusions, theories, and notions of conduct in life. They are conscious and unconscious imitators of each other, and are controlled by the thoughts and events which enter into each other's lives. Such intimacies are seen among students, clerks, business and professional men, and grow out of numerous complex conditions. These men frequently possess a clinging emotional nature, which is governed by the tides and events of each other's lives. They seem bound up in this way, and rise and fall with the person whom they are attached to. Some illustrative cases will make this class better understood. Two temperate business men, who had been intimately associated for twenty years, both became inebriates in this way; one had an attack of pleurisy, with a long, tedious convalescence, for which alcohol was given freely. The other, who was a constant attendant upon his friend, soon began to use alcohol for some supposed debility, and both of them drank to great excess, generally together.

Two farmers had been very intimate for years, and perfectly temperate. One went away to the far West, and was away for over a year, and returned a drinking man. The other, who was a pronounced temperance man, soon became an inebriate in the company of his friend. After drinking with more or less severity for two years, he moved away and reformed, and was temperate for a long time until his inebriate friend came in his company again; then he relapsed. They both separated and became temperate; then they came together and relapsed. Finally one died, and the other is a temperance man to-day.

The third case is more striking. Two railroad officials, who had been brought up together, and were temperate, healthy men, and very intimate in all their relations, both became inebriates. One became an inebriate from the loss of a trusted fund in a mining venture, which produced the most intense sorrow and depression of spirits. This was shared in by his friend and they both became intoxicated. For the next two years, whenever they met each other at intervals of a few weeks, both became intoxicated, and both were perfectly temperate when separated. The moment they came together old mental and physical depressions seemed to start up with great intensity, and the craving for spirits could not be resisted. One of the men travelled in Europe with a drinking party for several months, a total abstainer, and was separated from his friend for over a year and never drank. On one occasion they were separated for over two years and never used spirits, but both were intoxicated within two hours after meeting.

It will be evident to every thoughtful reader that the neurotic, strained, overworked business man, aspiring clerk and workman, have within themselves the favoring conditions and soil for the reception and growth of these mental contagions.

The inebriate is a diseased man, and can communicate his malady through these mental contagions as certainly as typhoid is communicated. Inebriety is a disease which should come under control of health boards, and its victims be quarantined and treated as positively as cholera cases or the insane. Then the evils of the malady may be reached, cured, and prevented.

Bullet-wounds of the Heart.—Dr. J. C. Neal, of Archer, Fla., sends the following note: "Referring to heart wounds reminds me that in 1877 I made a post-mortem of a desperado, who was shot directly through the heart and who walked some eight feet before he fell. Examination showed the ball passed through the heart centrally near the pulmonary artery, aorta, and upward through the left auricle, tearing the tissues frightfully, and yet he arose from a sitting posture and walked four steps before falling."

THE ETIOLOGY OF THE PLYMOUTH EPIDEMIC.

By WILLIAM STONE TORREY, M.D.,

SCRANTON, PA.

The cause of the recent epidemic of typhoid fever at Plymouth, Pa., has been the subject of much discussion, but there is no reason to believe that the cause has been finally settled, or that the subject has been exhausted. A short time since, the Luzerne County Medical Society appointed three of its members to investigate the matter, and to report to that body the result of their research. The report is embodied in Dr. L. H. Taylor's article which appeared in the number of the *Medical News* dated May 16, 1885. That paper was read before the Luzerne Medical Society on Tuesday, May 12th, and the theory advanced by Dr. Taylor as to the causation of the epidemic was accepted, and the subject was supposed to have been settled as far as that body was concerned.

I shall pass in brief review upon Dr. Taylor's paper, and endeavor to show that the cause advanced by him, although it undoubtedly acted as a factor, was by no means the prime factor in the production of the epidemic.

The author states that the town was supplied with water by means of four successive reservoirs, which reservoirs were fed by a mountain stream. On the banks of this stream, between the third and fourth reservoirs, is situated a house within which was confined, during a part of last winter, a typhoid-fever patient. The excreta of this patient were thrown upon the banks of the stream, and presumably, during the spring thaws, drained into the stream, and from thence flowed on into each successive reservoir, thus contaminating the whole body of water. From March 20th to March 26th water was pumped into the street mains from the Susquehanna River, and used for drinking purposes by the inhabitants. On March 26th the pipe leading from the lower reservoir was thawed out and the water allowed to flow into the mains. Dr. Taylor attributes the epidemic solely to the contamination of the reservoir-water in the above manner, and eliminates all possibility of infection from the river-water, stating that the lapse of time between the drinking of the river-water and the appearance of the epidemic on April 9th does not coincide with the recognized period of incubation for the disease. The period of incubation for typhoid fever, as stated by the most eminent authorities, varies from a minimum of three days to a maximum of twenty-eight days; so we conclude that this argument does not throw out the possibility of infection from the river-water.

It seems more reasonable to suppose that there were at least four factors present in the production and continuance of the epidemic, and that their action was manifested in the following order: First, contaminated river-water; second, contaminated reservoir-water; third, contaminated milk; fourth, contaminated air.

First, contaminated river-water. The water of the Susquehanna River has been demonstrated to contain a large quantity of organic matter. I grant that if it contained organic matter to the extent of one-third its bulk, in the absence of the specific element of the disease it would never produce typhoid fever; but I shall endeavor to show that the specific poison was there, and in large quantities too. The Susquehanna River receives the sewage, directly and through its tributaries, of all the thickly populated towns in this vicinity. This furnishes a fertile soil for the development of the specific poison of typhoid fever, should it gain access to it. The specific poison of typhoid fever is generally conceded to be contained in the excreta and to be cast off in a passive state. A period varying from one to two weeks is required for its development into activity, such development being accomplished in the presence of decomposing organic matter. Cold effectually stops putrefactive decomposi-

tion. As the typhoid excreta upon the banks of the mountain stream were thrown there in mid-winter, they must have remained in a passive state until it was too late for them to claim to be the causative agents productive of the *first* cases of the disease. Their activity comes into play later, after they have been acted upon by the sun and the poison is changed from a passive into an active state.

On the other hand, the river-water was polluted with the specific element of the disease as long ago, *at least*, as August, 1884. This pollution occurred at Pittston, a town about twelve miles above Plymouth, where from August, 1884, to February, 1885, there existed several hundred cases of typhoid fever. Now, all the sewage of Pittston empties directly into the Susquehanna. The excreta of these patients were disinfected with the sulphate of iron and then thrown into the sewers. The sulphate of iron has recently been shown by the New York Board of Health to be an inefficient disinfectant, and typhoid stools disinfected by it are not rendered inocuous. Now, *suppose* the excreta of all the patients affected with the disease at Pittston to have been disinfected with sulphate of iron (which was not the case), the specific element of the disease still existed, and upon being thrown into the sewers found a wonderfully fertile soil for its development. The whole mass of sewage thus leavened (by the addition of the specific poison) was being constantly poured into the Susquehanna River, and there met with a water containing a large quantity of organic matter, wonderfully qualified for its further development and the preservation of its vitality.

Typhoid fever is endemic in Pittston. The disinfection of the typhoid stools having heretofore been carried out imperfectly at that place, its sewers always contain the specific element of the disease, and are constantly discharging that poison into the Susquehanna River.

Second, contaminated reservoir-water. On March 26th the pipe leading from the lower reservoir was thawed out and the water allowed to flow into the street mains. The reservoir-water *was not at this time* contaminated, *but the pipes were*, on account of the river-water which they had previously contained. Consequently, upon the arrival of the reservoir-water into the pipes this becomes contaminated. A little later the typhoid excreta upon the bank of the mountain stream is being acted upon by the sun, undergoing decomposition and discharging itself into the reservoirs through the stream. Then the reservoir-water becomes polluted from behind, and thus the infection is kept up.

Third, contaminated milk. Milk is generally conceded to be fruitful in the conveyance of the typhoid poison. The milk must become infected in one of two ways—either by dilution with contaminated water, or through the cows drinking contaminated water, the poison being excreted with their milk. The cows must drink the contaminated water, as the water has been shown to be infected on every side. There is no reason to believe that the specific element in the production of typhoid fever goes to play a part in the economy of the cow; but it *is* reasonable to suppose that in circulating through the body it might contaminate the secretions of the animal, although unable to produce its specific effects upon it. We have daily illustrations of this principle in the human family. The mother's milk is frequently contaminated by poisonous principles circulating in her system, and the child, upon ingesting it, is affected specifically.

Fourth, contaminated air. The excreta of typhoid patients have not been thoroughly disinfected at Plymouth. These excreta were thrown into privy-vaults, cesspools, etc., and there found a soil well adapted for the development of their poisonous properties. The air becomes contaminated by these poisonous emanations, and thus another mode of infection is added.

It seems probable that all of these factors were present in the production and continuance of the Plymouth epidemic, and that the theory advanced by Dr. Taylor and accepted by the Luzerne County Medical Society, as being the sole cause of the epidemic, was only a factor, and by no means the most important one, in its production.

Clinical Department

SOME ADDITIONAL EXPERIENCES WITH COCAINE.

Dr. John A. Wyeth, of New York, writes as follows: "In December, 1884, Emily F. W——, of this city, came under my observation through the courtesy of Dr. William L. Wardwell. She had congenital cleft of the entire soft palate. The bones were not involved. The patient articulated very indistinctly, and with the nasal twang which is characteristic of cleft-palate. Operation was advised and performed in December, with the valuable assistance of Dr. Wardwell. A four per cent. solution of cocaine hydrochlorate was applied over the velum on either side, and along the edges of the cleft by means of a camel's-hair brush. This was repeated every five minutes for half an hour, at the expiration of which time sensation was entirely lost. I fixed the palate with a fixation forceps, and trimmed the edges to be approximated with a palate-knife. There was not the slightest sense of pain from the cutting. She said she felt that I was pulling the palate, but that it did not hurt. The operation lasted thirty minutes after the cutting began. The anæsthetic was applied every five minutes during the operation. The only pain experienced was when I divided the levator palati, palato-glossus, and palato-pharyngeus muscles, beyond the limit of the anæsthetic. I performed the same operation, three days ago, in the case of a girl, who was so timid that it was impossible to persuade her to try the local anæsthetic. Ether was inhaled, and it took two hours and a half to get through. With the local anæsthesia the sitting posture is maintained, the patient assists in holding the mouth open, the tongue out of the way, and in cleansing the throat. The procedure is greatly simplified.

"A medical gentleman in the Navy of the United States asked me to remove a tumor from the buccal mucous membrane of the left side. It was about half an inch in diameter, and situated half-way between the corner of the mouth and the opening of the parotid duct. By means of a very fine hypodermic needle I injected four minims of a four per cent. cocaine solution through the mucous membrane and into the substance of the cheek, one minim being forced out at four different points, equally removed from each other, and between three-fourths and one inch distant from the edge of the tumor. In five minutes' time the anæsthesia was complete, and I excised the growth in a circle half an inch removed from the periphery of its base. There was no sensibility in the tissues divided.

"A lady asked to be allowed to inhale chloroform in the removal of a painful in-growing nail of the great toe, which had caused a considerable ulcer on the inner side of this member. I injected four minims of a four per cent. solution of cocaine hydrochlorate beneath the skin near the base of the toe. Four points of insertion were selected in the track of the sensory nerves distributed to the half of the nail and matrix to be removed. The operation was painless."

A correspondent from Baltimore relates the case of a woman, suffering from a sore breast, in which suppuration was threatening. The gland was very tender, and the nipple was so excoriated that it was impossible to empty the breast. Hydrochlorate of cocaine, in four per cent. solution, was applied for a short time; the nipple was then washed with warm water, and the child nursed without causing any suffering. The excoriations were then dressed with finely powdered subnitrate of bismuth. The application of cocaine was repeated several times, and a speedy cure was obtained.

Dr. D. K. Shute, of Washington, D. C., relates the following cases, occurring in the practice of Dr. Sower:

The first case was one of a bursa, situated on the extensor tendons of the wrist in a young man. Seven minims of a four per cent. solution were injected into the bursa, which was then dissected away without causing any pain.

The same quantity of a like solution was injected into the substance of a fatty tumor, about the size of a walnut, lying on the posterior aspect of the neck in a young man. The tumor was enucleated without pain to the patient.

A boy, six years of age, was suffering from phimosis with strong adhesions. Five minims of the solution were injected hypodermically into the prepuce, and circumcision was performed. The child gave no evidence of pain during the operation.

A little girl, four years old, fell down, biting her tongue completely through for a distance of half an inch. An attempt was made to stitch up the wound, but had to be abandoned on account of the child's struggles. The wound and the portion of the tongue in immediate proximity to it were then painted over with a four per cent. solution of cocaine, after which the operation was painlessly performed.

The last case was that of a lady, forty-seven years of age, in whom catheterization was required for retention of urine. The catheter was introduced twice at intervals of five hours, but the operation caused very great pain and distress. A five per cent. preparation of the oleate of cocaine was then applied to the meatus five times at intervals of one minute, when the catheter was introduced with ease and with very little pain to the patient.

[We would suggest to our correspondents that, the local anæsthetic action of cocaine being now so well established, the occasion for reporting isolated cases no longer exists. Headache may be relieved or sleep procured by the use of bromide of potassium, but no one would think of reporting such a case unless it happened that the drug were given in a novel way, or that its administration were followed by peculiar results. And so it is now with cocaine. Cases which merely illustrate the fact that it will relieve or prevent pain are a matter of every-day observation, and, as such, no longer merit being reported.—Ed.]

HYSTEROTOMY FOR THE RADICAL CURE OF "PIN-HOLE OS."

Dr. Robert Ormsby, of No. 45 Vandam Street, sends a description of the method employed by him for the cure of this condition. Although the operation relieves the dysmenorrhœa, it has never, in the cases reported by him, cured the sterility. The method of operating is described as follows: "On examining the woman with a speculum it is of first consequence to locate the artery of the cervix. The pulsations of this artery can always be felt and may sometimes be seen. Either a Sims' or a bivalve speculum may be used. It is always necessary to straighten the uterus and drag it down, and when a bivalve speculum is used this also comes down, but does not interfere with the operation in any way. The instrument that I have always used for making the incisions is a long, narrow-bladed bistoury. The uterus being retained by a tenaculum, the bistoury is passed through the external os and then made to cut its way out. This operation is to be repeated until the knife goes very nearly as far as the internal os. Four incisions of this sort are made in different directions, so that the cut is cruciform in shape. The incisions can scarcely be too free, because the tendency to retract is very great. After this has been done the divided cervix is to be plugged tightly with styptic cotton, a tampon being applied to keep the plug in place. A suppository of about one grain of extract of opium is then to be given every four hours. The patient should remain in bed for ten days following the operation, the cervix being dilated every day with a pair of dressing-forceps. When the wound has entirely healed, and all danger of metritis is past, a uterine dilator is introduced and the internal cervix dilated to the extent of about three-fourths of an inch. This is done but once." Dr. Ormsby relates the histories of seven cases that were sent to him for operation. In none of these cases did the temperature rise above 101° F. A slight amount of pelvic cellulitis followed the operation in three cases, but in each of these there had been a chronic cellulitis existing for several years. In each instance the acute trouble was controlled within four days.

Progress of Medical Science.

Cure of Aneurism of the Abdominal Aorta by Laparotomy and Introduction of Silver Wire.—The attempt to cure an aneurism by coagulation of the blood through the introduction of foreign bodies into the sac has been tried on several occasions. Moore, in 1864, used iron wire; Lewis, in 1873, horsehair, of which he introduced about twenty-five feet into an aneurismal sac; Bacelli, fine watch-springs; Schrötter, in a case lately reported, introduced into an aneurism of the thoracic aorta 126 ctm. of Florence silk through a canula in divided portions at two insertions. This patient died fifteen days after the second operation, of pulmonary œdema, and the autopsy showed that the sac of the aneurism, which protruded from the wall of the chest, was entirely filled with coagulated blood. The peculiarity of the case now reported by Loreta, of Bologna, consists, not only in the eminently successful result, thereby differing from previous attempts, but in the fact that the aneurism affected the abdominal aorta and necessitated a laparotomy. The patient, a sailor, aged thirty, had suffered for two years. While hoisting sail he suddenly felt sharp pain in the epigastrium. Later he noticed a pulsation in the same spot, and in addition, pain developed in the region of the stomach, accompanied by disturbance of digestion, and numbness with pain in the lower extremities. The difficulty increased so much in the course of a year that the patient sought relief in the surgical clinic of Bologna. The examination showed the following facts: The man was pale and emaciated. In the epigastrium was noticed a pulsating tumor of the size of the head of a nine months' fœtus. Auscultation revealed a prolonged blowing murmur loudest in the left half of the abdomen. On these and other grounds the diagnosis was made of a sacculated traumatic aneurism of the aorta. In view of the discomfort, pain, and extreme emaciation, death was to be expected unless prompt relief could be given. Therefore, Professor Loreta concluded to perform laparotomy with the object of separating the aneurismal sack from the blood-current. The operation was performed on December 18, 1884. An incision was made from the ensiform process to the umbilicus. Strong and extensive adhesions between the peritoneum, omentum, and stomach were separated, the mesocolon was cut through, and the organs drawn aside till the tumor was exposed. The walls of the aneurism were so thin that it was feared that a ligature applied below the sac might produce rupture; the operator, therefore, concluded to introduce a wire into the sac to produce coagulation of the blood. With a slender trocar he made a puncture and carried through the canula as much fine silvered copper wire as the space in the sac allowed; in all, two metres. The outer end of the wire was also pushed in. The opening was touched with a concentrated solution of carbolic acid in order to shrink the tissues, the abdominal organs were brought back to their original position, and the wound sewed. The operation lasted an hour and a quarter. The same evening the patient no longer complained of the pains previously felt, and was able to sleep quietly, which had not been the case for weeks. On December 27th, the ninth day

after the operation, the first change of dressing was made; the wound was healed by first intention. The pulsation of the tumor was hardly perceptible, the murmur was very weak, the sac markedly diminished; the femoral arteries, which before the operation had shown only a weak pulsation, now pulsated very perceptibly. Twenty days after the operation no trace either of pulsation or of murmur was to be found, and the sac was about the size of a nut. The patient is now completely restored and can resume his occupation. Professor Loreta looks upon the use of the wire as the cardinal point of his success. This, at first, produced a coagulation, and later, on account of its thinness and pliability, opposed no obstacle to the shrinking of the clot. Although in only one of the cases above cited was death, which followed, supposed to be in any way attendant upon the interference, they tend to emphasize the uncertainty of the operation as well as the good fortune of Professor Loreta. It is very possible that these operations were too long delayed, however, and that an earlier resort to the procedure will prove more successful.—*The Boston Medical and Surgical Journal*, April 9, 1885.

Aphasia from Fright in a Child.—Dr. Demme of Bern, communicates to the *Wiener Med. Blätter* the account of a case of aphasia from fright in a child six years of age. The case was one of talipes equinus, and the division of the tendo Achillis was undertaken without an anæsthetic. Just before the operation, the child had been very lively and bright, playing with her doll and talking eagerly with her mother and brother. At the moment of the division of the tendon she uttered a piercing cry, after which she completely lost all power of speech. For about ten minutes she wept silently but copiously, and, when she had recovered herself, nothing that could be said would induce her to say a single word. This went on for eight days, during the whole of which time she was bright and lively, and answered readily by signs. On the morning of the ninth day she achieved the single word "Mamma," which she then used as an equivalent for everything else, and repeated thirty or forty times as a long sentence, evidently under the impression that she was thereby saying everything that she wished to convey to her hearers. On the fourteenth day her vocabulary was increased by several words, which were then made to do duty for all other words. On the eighteenth day she acquired a few more, and she never used one of these words in place of another on her list. She could not talk as well as she did before until the twenty-first day; but, after that, she developed bodily and mentally in a normal manner.

Gastro-enteritis Favosa.—The *Wiener Med. Blätter* contains the account of a recent lecture by Professor Kundrat on a case which he describes as one of gastro-enteritis favosa. The patient was suffering from favus universalis on admission to the hospital, and died from exhaustion after the development of a phlegmonous swelling in the right popliteal space. The necropsy showed traces of habitual indulgence in alcoholic liquor, and, besides, a very unusual condition of the mucous membrane of the stomach and intestines. In the stomach, where the mucous membrane was rugated and marbled, were found numerous punctated erosions, and yellow points and spots, and toward the pylorus a yellowish fibrous exudative membrane, firmly adherent to the injected mucous membrane. Masses of brownish mucus, of cadaveric odor, and mixed sparingly with fæcal material, were found in the large intestine, and also erosions of the mucous membrane, partly isolated, partly in groups, the edges of which were blackish, but not undermined. Similar appearances were noticed in other parts of the intestinal canal, giving the impression of having been caused by the presence of such a parasite as the favus germ. The fungus was, indeed, found in the exudation of the affected parts, differing from that found on the skin only by the threads being softer and the joints longer. Spores were also found; and the fungus was developed in such deep layers of the tissues that it was impossible to imagine its presence to be due to accidental mixture of the germs with the contents of the stomach. The spores could easily find their way to the digestive tract by the mouth, seeing that the whole body of the patient was covered with favus, but their development depended on an unhealthy condition of the gastro-intestinal mucous membrane which could be plainly seen to have been present in this case.

The Principal Antipyretic Drugs and the Mode of Recognizing them in the Urine.—Quinine gives a white precipitate with tannic acid; with solution of iodide of potassium and mercury (Tanret) it gives an abundant yellowish-white precipitate; with solution of iodide of potassium and iodine a brownish-yellow or chestnut-brown. The presence of salicylic acid, carbolic acid, resorcin, and kairin is shown by the addition of solution of the perchloride of iron (no reaction with quinine), which gives rise to a reddish-brown, wine-colored, violet, smoky, or bluish color. If, on the addition of sulphuric acid, the color becomes clear red, kairin is present; if the color obtained with the perchloride disappear on the addition of sulphuric acid, salicylic acid or resorcin is present. Carbolic acid with nitric acid gives a blood-red brown color and precipitate, with lively effervescence. Resorcin and salicylic acid are unaffected. Caustic potash, added lastly in excess, gives a golden yellow flocculent precipitate with resorcin; with salicylic acid the original violet color partly returns. If the urine be diabetic, to avoid error, it is well to boil it to drive off volatile products, such as acetone, which would falsify the reaction with the perchloride of iron.—*The London Medical Record*, April 15, 1885.

Antipyrin in Phthisis and other Febrile Disorders.—In the May number of the *Practitioner* for 1885, Dr. J. Holland, of St. Moritz, Switzerland, records his experience with antipyrin in the treatment of the febrile state, especially of consumptives. For years he has had many phthisical patients under his care, in fact he lived under the same roof with them. He was struck forcibly with the observation of the trivial causes that will cause the consumptive's temperature to rise. A little extra exertion, a political discussion, an attack of indigestion, a slight fall on the ice which has caused neither pain nor apparent injury, an attack of toothache—any of these things, which to a person in health might mean nothing, often tend in the sensitive phthisical patient to start a degree of fever which it is frequently difficult to suppress. Should the pyrexia continue for two or three days, we are almost certain to discover signs in the lungs of some fresh mischief; perhaps a little softening is detected over an area that had begun to dry up, or crepitation manifests itself in a part of the affected lung where, after careful examination, it had not been noticed before. This fever, then, is the first and earliest symptom of lung change, and must, in his opinion, be immediately attacked. Besides rest, even to the extent of confining one's patient to bed, and careful dieting, one must have recourse to medicinal remedies. Holland has generally found the following useful, although sometimes one and all have been extremely disappointing: quinine, the various preparations of salicin, digitalis, aconite, kairin, and Warburg's tincture are the principal drugs he has employed, and he finds they are more efficient when given in some effervescing form. For the last eight months he has been using "antipyrin," and he states that in his hands it has been more successful than all the other drugs put together. He concludes by saying that in cases of chronic fever, such as we have to deal with in consumption, antipyrin has no rival.

A Small Epidemic of puerperal fever is said to exist in the Cincinnati Hospital.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 6, 1885.

THE EPIDEMIC AT PLYMOUTH.

So thorough has been the investigation of the recent outbreak of disease at Plymouth, that we are able to draw fairly accurate conclusions concerning its etiology. As the various possible factors of causation have been analyzed, and the relative value given to each, it has become evident that the original theory, which referred all the cases to the contamination of the hydrant-water from the dejecta of the one patient living up on the hill, above the town, needs modification. That this would prove to be the case was foreshadowed in our editorial article of some weeks ago. The excellent communication on another page of the present issue, from Dr. Torrey shows conclusively that several agencies have been at work to produce the epidemic, and a study of the affairs at Pittston, nearly a year ago, makes it plain how the outbreak of fever could have occurred, even without the agency of the single case alluded to above.

Pathological investigations have conclusively shown that the disease is essentially typhoid in its nature. Some weeks ago it was a question as to whether or not some of the cases were only an expression of a malarial influence. The topography of Plymouth and the surrounding country is such that malarial diseases are always prevalent. The engrafting upon such diseases of a specific typhoid element would of course make a resulting change upon the clinical history of the cases. Even in hospital practice, where facilities for observation are at their maximum, it is a well-known and often-observed fact that the differential diagnosis between typhoid and malarial fevers (particularly of the remittent type) is by no means easy.

The mortality-rate has been about ten per cent. This is about the rate obtaining in city private practice among the better classes. It is less than our American hospital statistics indicate. The Germans, however, claim to be able to equal this figure in their institutions. This latter favorable showing may be in some degree due to national temperament and other environment. We think that the rate in the epidemic under discussion, considering all things, is low.

The lessons to be drawn from the whole matter are not new ones. No fact has been adduced that was not pretty well known before. The new causative factors which the study of the last fortnight has revealed, teach us not to be too hasty in drawing conclusions in matters pertaining to the etiology of disease. It was very fascinating to ascribe all the cases at Plymouth to one patient up on the hill-side, but his case has been shown, we think, to furnish not so much the origin as the continuance of causation. The epidemic has done much to strengthen the theory of the existence of a specific germ thriving on decomposing organic matter, which latter alone can never produce true typhoid. It may, however, cause a train of symptoms closely resembling it, the so-called "cesspool" fever. From both alike does the plea come for thorough sanitation.

LONDON DOCTORS.

A WRITER who signs himself "A Foreign Resident," but who is probably an American, has recently written a clever brochure upon Society in London, in which he devotes some pages to the doctors. A few of the leading physicians are sketched off with much spirit, if not with absolute truthfulness. In his introductory the writer makes some remarks which are probably true, and which should infuse hope into those who sometimes lament that the doctor is not so potent an element in human affairs as he ought to be. The men of medicine in England occupy now, says the "Foreign Resident," a peculiarly favorable position. The influences of the age are in their favor. It is in England the epoch of introspection. The English are always thinking that something is wrong with their morals, with their conscience, with their digestion, or with their lungs. And just now the attention which was once spent upon their ghostly sanity is spent upon their stomachs. The influence of the doctors upon diet is everywhere conspicuous, and it is the fashionable thing, according to the "Resident," for ladies and gentlemen in London society to carry about lists of prohibited dishes and drinks. We learn that the London doctors have made and unmade two things at least, viz.: wine-merchants and watering-places! So that men certainly are not quite without power in the world. As social representatives of the profession we hear only of Andrew Clark, Gull, Dr. Quain, Dr. Morell Mackenzie, Sir Henry Thompson, Sir Oscar Clayton, Jenner, and Paget.

It is instructive at times to learn how others look at us. We do not know that it would give entire pleasure to Sir Andrew Clark, however, to hear that he is said to be a combination of "a careful doctor and a good High Churchman." His happy faculty of oracular utterances, the solemn aphorisms with which he clinches his counsel to his patients, the sonorous platitudes with which he emphasizes the simplest of sanitary maxims, his quick eye, the kind severity of his manner, the air of judicial sympathy with which he interrogates those who come to see him upon their maladies, the calm deliberation, the systematic shunning of the semblance of haste—these are the qualities which cause London society to repose confidence in Sir Andrew Clark.

Sir William Gull, we are told, is endowed with all of Sir Andrew Clark's command of noble and sagacious sentiments. He plumes himself on his power of probing the secret hearts of his patients to their lowest depths by pregnant and pithy pieces of professional sententiousness. "It is worth paying a couple of guineas to store one's memory with the wise saws and modern instances

of which he is full." If he is not a great doctor, as many hold him to be, he is at least a marvellous piece of human machinery.

The more purely social side of the profession is represented by Dr. Quain, Sir Oscar Clayton, "who is admired because he has physicked, for more or less noble or ignoble ailments, the principal members of the aristocracy of England," Dr. Morell Mackenzie, and Sir Henry Thompson. Dr. Quain is not only "a Hippocrates of vast experience and profoundly scientific attainments, but a medical writer of the highest authority." He is withal a cheery, kindly, genial, gifted Irishman, and a medical philosopher of the epicurean type.

Dr. Morell Mackenzie is too entirely devoted to his profession to have much time to spare for social distractions. "He is probably one of the most gifted specialists in Europe, with one of the shrewdest heads on his shoulders."

Dr. Mackenzie gives large dinners, Sir Henry Thompson small ones. The latter "is an artist rather than an apolaust."

"Thus," concludes our author, "in Quain and Clayton, Mackenzie and Thompson, we have a quaternion of doctors who, in addition to the benefits they confer upon humanity by the exercise of the healing art, supply in the plenitude of their amiable thoughtfulness that social cement which causes society's various parts pleasantly to cohere. Such masters of medical science as Sir William Jenner and Sir James Paget constitute a more solemn class in the hierarchy of physicians. The latter is specially in favor with the Whig aristocracy, and the former is much occupied with the Queen."

THE SENSORY TRACTS AND CENTRES IN THE BRAIN AND SPINAL CORD.

The earnest and persistent efforts that have been made in the past fifteen years to localize the motor paths and centres in the cerebro-spinal system have been amply rewarded. Our knowledge in this respect has become positive, and is already helping to give definiteness to the diagnosis, and a larger scope to the therapeutics of nervous diseases. It was natural that the more difficult task of tracing sensory fibres to their terminations in the brain would be less easily and quickly accomplished. This work is now, however, being vigorously pushed, and all the more rapidly because new methods of studying the problem have of late been discovered. The paths of nerve impulses and their centres may be investigated in at least five different lines of research, viz., the anatomical, the embryological, the pathological, and the experimental, including the atrophy method of Gudden.

Results obtained by one method are thus checked off by those of others, and conclusions are reached which are very nearly positive and certain. Pursuing investigations in these various ways, Meynert, Flechsig, Monakow, Roller, Wernicke, Henle, Schwalbe, Exner, Munk, Luciani, Tamburini, and in this country Starr and Spitzka, have succeeded in accumulating sufficient data to enable one to describe the course of some of the sensory tracts from the periphery to the brain cortex.

As already stated, the course of the motor fibres, or a great part of them, has been established, and is part of ordinary anatomical teaching. A knowledge of the sensory paths and centres should, so far as possible, equally be made familiar to the profession.

We are indebted to the laborious and careful researches of Dr. Allen Starr for collecting and presenting many facts regarding this subject in a lucid manner (*Journal of Nervous and Mental Diseases*, July, 1884), and also to the classical monograph of Professor Luciani for presenting a very complete and precise account of the sensory functions of the cerebral cortex (*Brain*, July, 1884).

The sensory nerves from the skin and muscles carry special sensations of touch, and temperature, and general sensations of pain; the nerves from the muscles carry special sensations of locality (muscle sense) and general sensations of muscular sensibility. These sensory fibres all enter the spinal cord *via* the posterior spinal roots. Fibres carrying tactile thermic and painful sensations enter the gray matter of the posterior horns, and at once decussate probably in their entirety; the tactile fibres then pass up the spinal cord in the posterior columns. There is some evidence, which is, however, not conclusive, that the fibres from the lower extremities pass up in the posterior median columns (columns of Goll), while those from the upper extremity pass in the posterior lateral columns (columns of Burdach). The thermic and pain fibres pass up in the gray matter, or in the posterior columns. Reaching the medulla, these fibres, tactile, thermic, and pathic, pass through the inter-olivary body and formatio reticularis; they continue on in the pons and crura, passing in the formatio reticularis and lemniscus, and in the crura lying in the outer half of the tegmentum. Leaving the crura, the sensory tract passes in the inner half of the posterior third of the internal capsule. From here the fibres enter the corona radiata and are distributed to the cortex of the central and parietal convolutions. The fibres carrying the special muscular sensations (muscle sense) appear not to decussate upon entering the cord, but pass up in the posterior columns and decussate in the medulla; they then join the sensory tract and are distributed with it as above described.

On the ground of analogy with other special sensations, it has been suggested that the sensory fibres of the cord do not entirely decussate, but that a smaller part continue up on the same side as that from which they originated. Clinical and pathological facts hardly support this view, while the laborious experiments of Luciani appear to show that the decussation of tactile and muscular sensations is complete. The termination of the sensory tracts in the central convolutions, where they impinge nearly upon the same areas as those known as the motor centres, is tolerably well established by the experiments of Munk, Tripier, Moeli, Luciani, and Sepelli, and the researches of Exner and Starr. Luciani shows, however, that in monkeys and dogs at least, no definite sensory areas can be mapped out, but that these areas are diffused and overlapping. He also shows that for other special senses, and probably for the tactile, the cortical sensory areas are not absolute centres, destruction of which causes permanent anæsthesia. They are rather psychical centres, where sensory impulses received elsewhere are collated and the act of perception occurs.

As regards the other special senses, the researches of Luciani appear to be more exhaustive and conclusive than those of previous observers. They support in a

great measure those of Munk, but contradict in many respects those of Ferrier and Goltz. The cortical visual centres are most "intense" in the occipital lobes, but they diffuse and overlap other centres in much the same way as Exner described. From each hemisphere the larger part of the fibres pass to the inner segment (of about two-thirds) of the retina of the eye of the opposite side, while the remainder pass to the external segment (about one-third) of the retina of the eye of the same side. This fact, which Munk first proved clearly, is now well established. As to the exact nature of these cortical centres, it has generally been stated, on the authority chiefly of Munk and of Ferrier and Yeo, that, when they are extirpated on both sides by destruction of both occipital lobes, permanent absolute blindness results. Professor Luciani, however, asserts very positively that in monkeys and dogs, where these centres are entirely extirpated, the result is a temporary blindness, followed by a permanent psychical blindness, *i.e.*, a condition in which the animal sees objects, but does not appreciate their nature. It sensates, but does not perceive. Hence these sensory cortical areas are centres for visual perceptions. In their destruction there is lost the memory of previous sensations and the power of associating them, just as after destruction of the cortical motor centres there is lost the memory of the association of movements, the animals recovering from complete paralysis, but moving in a clumsy and unintelligent way (Goltz).

The area of the auditory centre undoubtedly lies in the temporal lobe. From here it appears to extend upward to the parietal convolutions, forward to the frontal, backward toward the hippocampal, inward toward the cornu ammonis. As with vision, each ear is connected with the auditory areas of both sides, but much more largely with the area upon the opposite side. In opposition to Munk, Professor Luciani here asserts again that a bilateral extirpation of both auditory areas causes only psychical deafness.

For the sense of smell, the centre of the sensory area appears to be in the gyrus hippocampus and cornu ammonis. With the olfactory nerve the direct fasciculus appears to be greater than the crossed, in this respect differing from the arrangements of the visual and auditory fibres. The sense of taste seems to have its cortical centre in close anatomical relation with that of smell.

HOW SHALL THE PHYSICIAN WASH HIS HANDS?

Experienced observers have noted with gratification the revolutionary effect of antiseptic theories upon the washing habits of the surgical artists of Germany. It has been accepted as a basal fact that washing, and even nail-cleaning, are really indispensable parts of professional work, and these practices have therefore been patiently and conscientiously carried out. There is no greater evidence of the innate heroism of the Teutonic character. Mr. Matthew Arnold may accuse the Germans of lacking civic courage, but not of personal self-abnegation.

But having settled the immense fact that washing is a good thing, another step has already been taken, and searching and scientific inquiries are being instituted as to how this washing shall be done. "Wie soll der Arzt seine Hände reinigen?" is the title of a paper by Dr. Wassing in the *Archiv für Hygiene*, and of one by Professor J. Forster in *Centralblatt für Klinische Medicin*, No. 18, 1885.

The subject is discussed seriously and fruitfully, as it ought to be. Dr. Wassing, working under the direction of Professor Forster, discovered that the ordinary methods of washing the hands with soap and water did not make those members aseptic. For example, the hands, after being washed, were dipped in solutions (of various strengths) of carbolic acid, boracic acid, zinc and iron chlorides. They were then immediately protected with sterilized wadding or cloth, and the finger-point was applied to sterilized, feebly alkaline, neutral, or acid peptone-solutions or culture-gelatine. In every case, without a single exception, bacteria developed in these fluids within twenty-four to sixty hours. It was thus found that the ordinary practice of washing the hands in a two and a half per cent. carbolic solution, or even the method recommended by Billroth, of cleaning the hands with muriatic acid and a ten per cent. solution of phenol in glycerine, was not sufficient to prevent inoculation of sterile fluids by the fingers. By washing the hands in soap and water, however, and afterward in sublimate solutions of the strength of 1 to 1,000 or 1 to 2,000, they are made perfectly *pilzfrei*, and sporeless and safe.

The conclusion is that, surgically speaking, all the world has dirty hands, and that the physician and the surgeon always carry some living spores about them, unless they adopt these special means for disinfection. It is not claimed, however, that these almost inseparable parasites are necessarily harmful, or that manual asepsis by the sublimate is always absolutely necessary. But it is certainly well to know whether the hands are sporeless or not, for there are occasions when perfect disinfection is desired.

Professor Forster suggests the sublimate purifications in connection with obstetric cases, post-mortem examinations, and in dealing with the acute infective diseases. A good deal is accomplished when the hands are disinfected, but not all, for the virus may be carried by the hair and the clothes.

DIET AND DYSPEPSIA.

It is not surprising to find that directly antagonistic views to Dr. Flint, as to diet and digestion, are held by Sir Henry Thompson. In nine cases out of ten, says Sir Henry, in a recent article in the *Nineteenth Century*, dyspepsia is simply the result of a stomach trying to digest what it can't. All that a person needs, then, is to select what agrees with him, and he has but little trouble with dyspepsia. In other words, if the chronic dyspeptic will diet himself, he can generally live as comfortably as any one. This is so obviously the correct view that it needs little argument for its support. The modern stomach has become a somewhat fastidious organ. It has in many cases to be treated gingerly—we do not speak in an officinal sense. Thousands of men go through life, examples each day of some prandial self-abnegation. Every now and then they try to teach the stomach wider and more catholic views, but the viscus is obstinate, and the owner is forced back to his Spartan

regimen. "For most men," continues Sir Henry, "dyspepsia is the penalty of conformity to the eating habits of the majority; and a want of disposition or of enterprise to undertake a trial of simpler foods than those around them consume probably determines the continuance of their unhappy troubles. I have for some years past been compelled, by facts which are constantly coming before me, to accept the conclusion that more mischief in the form of actual disease, of impaired vigor, and of shortened life, accrues to civilized man, so far as I have observed in our own country, and throughout Western and Central Europe, from erroneous habits in eating than from the habitual use of alcoholic drink, considerable as I know the evil of that to be."

News of the Week.

The Insanity of Victor Hugo.—Some ingenious Frenchman has tried to show that Victor Hugo was insane. A case of this kind can be made out against nearly every man of striking and original genius. Yet there was undoubtedly a psychopathic taint in Hugo's blood. His father died of apoplexy, his mother was a woman of a somewhat eccentric character, who died of phthisis. Hugo himself was a sickly child. His early pictures show him to have had an immense, hydrocephalic-looking head. One of his brothers died insane, one son died of congestion of the brain, another of, we believe, phthisis. Hugo's admirers try to show that his life and character were consistent throughout. In fact, however, there was much of the *bizarre* and extravagant, of the contradictory, and even ridiculous, in his acts and writings. He was, in truth, a veritable illustration of the genius that is to madness close allied.

That Falls from Great Heights are not necessarily fatal is shown in the case of a soldier, who, in consequence of the torture produced by an insect-bite in the ear, jumped from the bank of a cañon into the Rio Grande, a distance of 155 feet. He was picked up alive, and was walking about next day.

The Woman's Medical College of the New York Infirmary held its seventeenth annual commencement on May 29th. A class of eleven was graduated, among whom was one young woman a native of China. The graduating class declined to receive flowers, as giving the exercises too much of a boarding-school flavor. The address was delivered by Dr. E. H. Janes, Professor of Hygiene. Dr. Emily Blackwell, Dean, made an interesting report, showing the effect of attempts to raise the standard of the curriculum upon attendance. When the course was lengthened to three years, the number of pupils fell off one-half. This falling-off was gradually recovered from. When an entrance examination was made compulsory, attendance again fell off one-half. The college is now regaining again its former numbers.

A Scandal in Connection with a Proposed New Medical College.—At the last session of the State Legislature, the notorious Dr. Gunn, of this city, succeeded in getting a bill passed, incorporating a "College of Medicine and Surgery" in this city. The bill has been before Governor Hill for his signature. While making an argument in its favor last Monday, Gunn created a sensation by stating that Senator Coggeshall had solicited a bribe of $500 for his vote and influence. Whatever the fact regarding this may be, the prospect of a new medical school under Dr. Gunn is not a pleasant one, and our County or State societies should have looked after it.

Death of Dr. Hannan.—Dr. John C. Hannan, of this city, died on May 27th, in his forty-second year. He was a native of Limerick County, Ireland, and received his education partly at Queen's College, in Cork, and partly at the Medical School at Columbia College, having come to this country when about twenty years of age. Since 1866 he had been in practice as a physician in this city.

Russia Declines the Help of American Surgeons.—Some weeks ago, when the prospect of an Anglo-Russian war was thought to be possible, two physicians of Detroit, Drs. Ranney and Post, tendered their services to the Russian Government. The Russian Secretary of Legation returned the following reply: "D. H. McComas, Esq., Deputy Secretary of State, Lansing, Mich.: Sir—In reply to your letters of April 10 and April 21, 1885, in behalf of Drs. Ranney and Post, I beg to say that foreigners, physicians and surgeons, are allowed to exercise their profession in Russia only if they obtain in one of our academies of medicine the necessary diploma, delivered after successful examination before a Board of Professors. Diplomas of foreign institutions are not sufficient, and the lack of knowledge of the Russian language will, without doubt, create great difficulty. I understand that, considering the great number of our own Russian surgeons, there is not a special need of enforced help at present, and do not know of any intention of our Government to facilitate (?) now to foreign doctors the exercise of their profession. I remain, sir, very respectfully, A. Greger, Secretary of Legation." This is probably the first intimation that Russia had "a great number of surgeons." Statistics show that Russia has the smallest number of medical men to the population of any civilized country, while, since the death of Pirogoff, there is hardly a Russian surgeon known to science.

Blackwell's Island Lunatic Asylum, New York.—Two vacancies exist on the resident staff of this institution. The term is unlimited, and there is a small salary, with progressive promotion as resignations occur. Application may be made to Dr. T. M. Franklin, Medical Superintendent.

A New Chair.—The authorities of King's College, London, have created a Chair of Clinical Therapeutics, and appointed Dr. Burney Yeo to occupy it.

Prohibiting Assessments for Railroad Hospitals.—According to the *Fort Wayne Journal of Medical Sciences*, the plan adopted by several Western railroad companies of assessing employés for purposes of sustaining a hospital has not been acceptable to many of them, "in fact, some have protested against it, and have been doing all that they could do to make the plan unpopular, and through their influence have succeeded in securing the passage of a law by the late Legislature prohibiting railroad companies from collecting assessments for hospital purposes."

Progress of the Cholera Vaccination Experiments.—Dr. Ferrán has been conducting his inoculation experiments on a large scale in Alcira, a town of upward of twenty-five thousand inhabitants, situated about twenty-five miles distant from Valencia. Almost immediately upon his arrival, when the object of his visit was made known, so many people presented themselves for vaccination that the virus was exhausted, and he was obliged to return to Valencia to prepare a fresh supply. A correspondent of *Las Provincias*, a newspaper of Valencia, writes that when Dr. Ferrán, in company with Dr. Pauli, arrived the second time in Alcira, they were greeted with almost an ovation, and crowds of people of all classes flocked around them to be inoculated. At the time of writing over two thousand two hundred persons had already been vaccinated, and there was apparently no diminution in the numbers of those who were waiting their turn, and the correspondent predicts that there will hardly be an individual in the city who will not have been inoculated at the expiration of Dr. Ferrán's visit. Two girls, in an asylum where the inoculations had been practised, had for some reason been passed over, and both of them were subsequently attacked, the other inmates remaining free. This occurrence soon became known, and created a profound sensation, inducing many, who had hitherto been incredulous or indifferent, to present themselves for vaccination. Outside of Alcira, also, the enthusiasm over Ferrán's experiments continues, and the journal *La Independencia Médica* has established a new department, called the "Sección Ferràniana," which is to be devoted exclusively to reports of these inoculation experiments. In the last number received of that journal two-thirds of its space is given up to this subject. In the presence of experiments on so large a scale as those of Alcira, we shall not long be left in doubt as to the value, or otherwise, of Dr. Ferrán's discovery.

Cremation in Spain.—A bill is about to be introduced in the Spanish Cortes allowing cremation of the dead. It is to be done, however, only when the individual has so signified his desire before death, and will not be permitted on the simple request of the relatives. Before cremation a medical certificate must be obtained, declaring that the person died of natural causes, and if there are any suspicious circumstances connected with the case burning of the body will not be permitted. Before the bill is promulgated, it is stipulated that crematories shall be prepared and places provided where the ashes may be kept free from the danger of profanation.

Effect of Fright on the Mind.—Under this heading, the New York *Sun* of a recent date gives a very interesting account of the actions of the crowd during the great earthquake at Ischia. The article is none the less interesting for having been taken almost word for word, but without credit, from The Medical Record of November 8, 1884.

A New Law Regulating the Practice of Medicine in Indiana was recently enacted by the State Legislature. The law simply requires that all persons practising medicine in that State shall obtain a license from the Clerk of the Circuit Court. Such license is given to anyone who has a diploma "from a reputable medical college," or who has practised in the State for ten years, or who has practised in the State for three years, and attended a single course of medical lectures. The practical effect of such a law as this will be simply to give a legal status to all the quacks in the State. Experience has shown that such laws are bad in their effect. Their only justification is that they sometimes pave the way to better legislation.

Death of Dr. Simon V. Pilgrim.—Dr. Simon V Pilgrim died last Saturday, after a lingering illness caused by malarial fever, at his house in this city. He was born fifty-one years ago near East Broadway. After being graduated from the New York Medical College, he began practising at Honesdale, Pa., but at the beginning of the war went into the service as assistant-surgeon. He afterward became a regular surgeon, and ranked as major. While stationed at Port Hudson he had malarial fever, which more or less affected his health during life. When peace was declared, Dr. Pilgrim came to New York, and settled down in his old home in Cannon Street. He became prominent in that part of the city, and took an active interest in local politics, being a stanch Republican.

Good Men Falling Out.—When one distinguished apostle of the "higher" ethics calls his brethren and allies "a lot of scheming, wire-pulling, half-cut editors," and when one of these latter retorts by calling number one, in unethical alliteration, "a jaded, journalistic gelding," it is time to ask, Where is the Angel of Peace and Goodwill that is supposed to hover over the sacred Ark of the Code? *Tantæne iræ celestibus animis?* If so, we recommend a little more of the four Gospels, and less of the medico-political righteousness developed at meetings of the American Medical Association.

Two Cases of Cholera have appeared at Marseilles.

Dr. Burdon-Sanderson on the Cholera Bacillus.—Dr. Burdon-Sanderson, in a recent lecture upon cholera, offered the opinion that Koch's view as to the significance of the cholera bacillus was "an unfortunate fiasco.'

The International Medical Congress.—The *Philadelphia Medical Times* shares the view of The Record, that the Executive Committee appointed to arrange for the next International Congress was given full power, and is not responsible now to the American Medical Association, but to the medical profession. Our contemporary suggests that the new committee appointed at New Orleans to succeed it act as an advisory body. Unfortunately, this committee legally either has the supreme authority, or else it is no committee at all.

The Last Sickness of Victor Hugo.—The Parisian press teems with the details of the last illness of Victor Hugo. It seems that he suffered from congestion of the lungs. He had attacks of dyspnœa and was at times delirious. The last bulletin published was as follows: "The night has been restless and troubled by two suffocating fits. A certain degree of congestion is noticed in the right side this morning.—Professor Germain Sée, Dr. Vulpian, Dr. Emile Allix." From the beginning of his illness several bulletins were issued daily by the attending physicians.

The International Sanitary Conference.—The International Sanitary Congress met for the first time in Rome on May 20th, and was welcomed by the Minister for Foreign Affairs, Signor Mancini, who said that the duty of the Conference would be to concert preventive measures, to be enforced in each country, to prevent the introduction of communicable diseases, or to stamp them out at their outbreak, and also to make arrangements to adopt a rational and practically useful method for protecting other countries from invasion. Signor Mancini having declined to be nominated President, Count Cadorna was elected. The Conference adopted the rules in force at the Vienna Conference, constituted its bureaus, and then adjourned until Monday, May 25th. Dr. Sternberg, delegate of the United States, presented copies of the protocols of the Conference held at Washington in 1881. It has been generally understood that the Conference will sit for about a month at the present time, and that if the business before it is not then completed, its sittings will probably be suspended during the hot weather.—*British Medical Journal.*

The Berlin Cholera Conference.—This conference, of which we have already given some account, terminated on May 8th. The discussions covered mainly the subjects of the etiology and prevention of cholera. It can hardly be said that much which is new was elicited. Dr. Koch summarized the chief measures that could be taken against cholera as follows: 1. Measures should be adopted by which the infectious matter be directly destroyed, disinfection of the dejecta, destruction or thorough disinfection of the linen, etc. 2. Sanitary measures should be adopted for removing the infectious matter from the vicinity of human beings; for example, drainage, provision of good water for drinking and household purposes. 3. There should be a supervision of the population by experts, in order that the very first cases might be diagnosed, and that the epidemic may be nipped in the bud. The patients must be isolated. Houses in which people had been attacked must be evacuated; that is, the inhabitants not yet attacked must be removed and placed under supervision. 4. The public must be instructed. Their attention must be drawn to the danger of using infected food—for example, uncooked food, and well-water that had not been boiled, and they must be warned against the use of infected linen.

Dr. William Clendennin, of Cincinnati, Dean of Miami Medical College, died of catarrhal pneumonia last week, in the fifty seventh year of his life.

Partenine.—This is an alkaloid, said to possess valuable antipyretic properties, extracted from the *Parthenium hysterophorus*, or feverfew, by Carlo Ubrici, an Italian chemist. It occurs in the form of black, shining, brittle scales, which are easily pulverized, the powder being of a light gray color. It has a peculiar taste, not bitter, but leaving a pleasant aromatic taste in the mouth. It is soluble in cold water, the solution being yellow, red, or black, according to its strength. It is well tolerated by the stomach in doses not exceeding thirty grains. Dr. G. R. Tovar has used this alkaloid in a number of cases in the place of quinine, and expresses himself as well pleased with its antipyretic action.—*Raccoglitore Medico.*

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF OHIO.

Fortieth Annual Session, held at Dayton, O., June 3, 4, and 5, 1885.

(By Telegraph to The Medical Record.)

First Day—Wednesday, June 3d.

The Session was opened with prayer by Rev. Mr. Hale.

Dr. W. J. Conklin, President of the Montgomery County Medical Society, made the

ADDRESS OF WELCOME

of this third visit of the Society to Dayton, and gave the freedom of the city.

The Secretary reported 567 members; also that Dr. J. P. Thompson, who recently died, donated his set of proceedings, the only complete one extant, to the Society.

Dr. J. F. Baldwin, Chairman of the Committee to secure

A STATE BOARD OF MEDICAL EXAMINERS,

reported no progress. The ten so-called regular physicians in the House formed the most potent faction against the bill. The bill was defeated by three votes. The report

RECOMMENDED THAT THE SOCIETY USE ENDEAVORS TO KEEP DOCTORS OUT OF THE LEGISLATURE,

and to ask for nothing if we would not be disappointed.

Dr. Herrick, Chairman of the Committee on Legislation, reported that

NO BILL RESTRICTING MEDICAL PRACTICE WOULD BE ENTERTAINED BY THE LEGISLATURE,

and that the Society must confine itself to securing improvements in sanitation.

One member from each county was added to the Committee for the collective investigation of disease, to get a more thorough representation of the State.

Dr. C. A. L. Reed, of Hamilton, read a paper on

PELVIC HÆMATOCELE.

He thought there was much of fiction in the common remark that there is no danger from the puncture of a trocar. He favored the evacuation of coagula, and thought that the demands of science and humanity called for some means of controlling the initial hemorrhage. He believed that the operation by incision along Poupart's ligament, and the elevation of the peritoneum, was a valuable procedure in cases in which the accumulation lay beneath the broad ligament. In view of the extreme probability of septic troubles we were justified in some simple expedient to control the initial hemorrhage. This could be done by simple ligation of the vessels beneath the broad ligament. It was not the serious operation it had been pictured.

Dr. Miller made the incision where he could obtain the best possible drainage. Nature took care of the majority of cases, unless the extravasation of blood was great. He did not believe in hurried operations, nor in waiting. What was death in one case was life in another. In some cases he would not operate at all.

Dr. Herrick spoke against operation for evacuation.

Dr. John Carson, of Middletown, favored early operations.

Dr. Kenzon, of Houston, and Gay, of Columbus, continued the discussion.

Dr. Palmer read a paper on

A RARE COMPLICATION IN OVARIOTOMY.

He commented on the of late general successful course

and termination of ovariotomies, and said the relating of the common run of cases presented but little interest. Every now and then, however, extraordinary, rare, exceptional, or unheard-of complications occurred. These experiences, for the guidance of the operator and the perfection of the literature, should be both mentioned and recorded. With this object he presented the following case :

Miss ——, German descent, blonde, of delicate organization, noticed at the age of nineteen, which was three and a half years ago, an abdominal enlargement. It was central, regular, and uniform. Later, when the tumor had arrived at about the size of the child at term, she consulted a physician. He, in consultation with another, diagnosed abdominal dropsy from Bright's disease and tapped her. The abdomen completely collapsed. The process repeated itself. She applied for relief at one of our hospitals, where the same diagnosis was made. She was here again tapped with the same result. Again she was tapped by a third physician. At each operation about a bucketful and a half of fluid was drawn off. The tappings, numbering eight in all, occurred between June 3, 1883, and October 30, 1884—seventeen months in all. The fluid was at no time especially thick.

Her last attendant, Dr. John Kellar, suspecting that her true condition might not be ascites, asked the author to see the case with him. He found the abdomen immensely distended. Fluctuation was very distinct, superficial, and uniform. There was also dulness extending backward to an unusual degree. Lateral decubitus showed a slight change in the area of dulness. No fluctuation could be felt in the posterior cul-de-sac. The patient was very anæmic and feeble ; pulse, 120 to 130 per minute ; febrile movement was noticed each evening. The menses had been absent for six months, and the lower extremities were swollen and œdematous. No albumen was found in the urine. Diagnosis : Ovarian cyst of the unilocular variety. In view, however, of the former diagnoses, and the fact that there were some obscure points in the history and in the present physical signs, an exploratory incision was made. This confirmed the diagnosis. Her general condition was the most unpromising for an ovariotomy, and the hygienic surroundings were also unfavorable.

The abdominal wall being opened, the cyst wall was found closely adherent in all directions to the abdominal walls. When these adhesions were broken up, as far as could be reached by the finger, a large amount of fluid began to flow through the abdominal opening. For the instant this was thought to be ascites, and the patient was about to be turned upon her side to aid in its evacuation, when the true source of the fluid was found to be two lacerated fringes which entered the interior of the cyst. This opening was directly opposite to a cicatrix in the abdominal wall, and had been made by the repeated tappings. Through this some cystic fluid had doubtless flowed into the peritoneal cavity after some of these tappings. Subsequently its edges had been aglutinated by peritoneal adhesions to the abdominal walls. Two other and smaller openings were also found. The smaller openings were clamped with hæmostatic forceps, the larger plugged with a large-sized ovariotomy trocar, through which the cyst was drained. This was almost completed before it was attempted to detach the cyst from its surroundings. Adhesions were short, thick, firm, numerous, and uniform over whole anterior and lateral abdominal walls, also to the omentum, stomach, and colon.

The pedicle to the right ovary was transfixed, and cut off about one inch from the seat of ligation, after which a wedge-shaped section was cut out of the fore end and the peritoneal edges were sewed together by a continuous stitch of catgut. This was the author's manner of dealing with the pedicle in his last five ovariotomies all of which terminated successfully; it possesses advantages against secondary hemorrhage and septic absorption. Oozing was controlled, and the peritoneal cavity cleaned of all fluids. The abdominal cavity was closed with silk sutures without a drainage-tube. Strength was sustained by brandy hypodermically.

The operation left the patient in a forlorn condition, but she began immediately to improve. Fearing vomiting, all food was given per rectum. A low form of peritonitis occurred during the first week, attended with tympanites and dyspnœa ; pulse, 140 ; temperature, 103° to 104° F. On the eighth day a fatal result seemed imminent. Two stitches were removed and a rubber tube inserted, removing eight to ten ounces of fetid serum. The temperature fell three degrees in two hours ; all other bad symptoms improved accordingly. Convalescence a few days later seemed established, and recovery seemed certain, when another complication appeared. On the twelfth day a smell of gas with a fecal odor was noticed at the opening made into the abdominal cavity. The next morning a small amount of fecal matter was seen and removed. A fecal fistula had formed. It seemed to communicate inwardly with the lower small intestine, and the external opening presented midway between the umbilicus and symphysis pubis. At first it discharged daily several ounces of fecal matter, and has continued to discharge since in quantities gradually diminishing and less offensive. The present quantity averages daily two to three teaspoonfuls.

For two months the recovery has been complete, except for the fecal fistula. It is possible that this may close spontaneously. No treatment for the fistula has been undertaken, except the regulation of the diet and the use of a compress ; surgical interference may yet be needful.

The occurrence of this fecal fistula is one of interest and rarity. It is a question how this one appeared. The most reasonable and plausible explanation would be that the intestinal perforation resulted from softening from the peritonitis. The septic fluid remaining would have certainly led to a fatal termination had not the peritoneal cavity been opened when it was. Baker Brown, in " Ovarian Dropsy," gives examples of avenues for the escape of ovarian cystic fluid. Instances of fecal fistula are given by Milner Moore (*The Lancet*, 1880, vol. i., p. 329) ; Bantock (*The Lancet*, 1879, vol. i., p. 207). Atlee, Peaslee, Simpson, Barnes, Thomas, Emmet, Goodell, and Tait make no mention of any case. Spencer Wells mentions three cases, one his own, the only one in his one thousand reported ovariotomies. Mr. Bryant (" Guy's Hospital Reports," vol. xiv., p. 228), Pouchin and Kuffrath (*Belgian Med. Press*, 1880, vol. xxxi., p. 217), and Kuswein (*Centralblatt für Chirurgie*. 1879, p. 630) report cases.

It is remarkable that such perforations do not occur more frequently. This may also be said of lacerations of the intestinal tube. The tumor is often adherent to these parts, and separated only with the greatest patience and skill. Bantock and Barnes (*The Lancet*, 1877, vol. ii.) report such cases.

Considering the facts, the author asked, Is it not possible that lacerations and perforations are more common than is supposed ?

Dr. Dunlap, of Springfield, in discussing this paper, reported two cases of fistula. After ovariotomy, one appeared at the end of the third week, and continued six weeks. The patient made a perfect recovery.

Dr. Dillon, of Cleveland, thought Dr. Palmer's case would terminate successfully. He had a case of fistula, occurring on the fourteenth day, which remained open three months. The patient recovered and married. Both of her ovaries were in the doctor's office, and she still menstruates.

Dr. Palmer said the majority of these fistulæ close within one year. Should they not do so, it would be advisable to make an operation to close it. It is a most difficult operation, and has been followed by fatal results. It should not be made unless positively necessary.

(To be continued.)

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Thirty-sixth Annual Session, held at Scranton, Pa., May 27, 28, and 29, 1885.

(Concluded from page 604.)

SECOND DAY—THURSDAY, MAY 28TH.

OFFICERS ELECTED.

DR. WOOD, of Pittsburg, was elected President, and Drs. McGowan, Ross, Shaffer, and Halsay Vice-Presidents; Dr. Atkinson, Permanent Secretary.

THE COMMITTEE ON MEDICAL EDUCATION,

appointed last year, recommended the following propositions:

First, that the sole power of granting license to practise medicine in Pennsylvania should be vested in a single board.

Second, this board should have no connection with any corporation engaged in medical teaching.

Third, the doings of this board, including the determination of the fitness of applicants for the license to practise, should be public and matters of record, and the records open to public inspection.

Fourth, to secure the efficiency of the board against incompetent membership and the undue pressure of partisan politics, the medical profession or its representatives should nominate to the Governor a list of persons qualified to perform its duties, from which list the board should be appointed.

It also recommended the appointment of a committee to prepare a bill for presentation to the next biennial session of the Legislature, and to report the same at the next annual meeting. The resolution was adopted, and the committee continued.

A draft of an act, prepared and recommended by the American Medical Association, in relation to the appointment of State Boards of Examiners, was also referred to a special committee.

DR. TAYLOR, of Wilkesbarre, read a paper on

THE PLYMOUTH EPIDEMIC.

He had, with a committee of Wilkesbarre physicians, made an exhaustive investigation of its etiology, and determined the cause was poisoning of the mountain stream which supplies the town, by the excreta of a single typhoid patient. The doctor carefully stated other possibilities, as, for instance, the pumping of the Susquehanna River water for one week into the mains while the mountain supply was frozen, March 20th to 26th. The first case occurred about April 10th, giving, he thought, too long a period of incubation if the river-water were the cause.

DR. SHAKESPEARE confirmed the statements and conclusions of Dr. Taylor. The diversity of opinion on this matter has divided physicians and the public, in this region, into two parties, "Mountain-stream" and "River-water" theorists. For the latter it must be said that though the hemorrhagic dejecta of the mountain patient were thrown on the bank of the stream for weeks, they were not thrown *into* it, but on the snow fifteen or twenty feet from its edge; and that the river is unquestionably poisoned by Wilkesbarre's sewage from 30,000 people (within two and one-half miles), and by that of Pittston, Scranton, and intermediate points. The element of time bears equally on both the theories, as cases keep still occurring.

Until a specific typhoid germ is *demonstrated*, perhaps it would be well not to insist too strenuously on either exclusive theory, but to admit the concurrent causes mentioned in THE MEDICAL RECORD'S editorial of May 16th inst. The mortality remains at ten per cent.

THE ADDRESS IN MEDICINE

was made by DR. EDWARD T. BRUEN, of Philadelphia, who stated that the causal importance of the bacillus of tuberculosis was claimed by an increasing number of clinicians and pathologists. Cases of abdominal tuberculosis existed in which it cannot be found.

Referring to the cholera bacillus of Koch, and the microbic theory of diphtheria, without definitely indicating his acceptance, the Doctor recommended the propriety of boiling drinking-water and the free use of corrosive sublimate or sulphate of copper as disinfectants, the flushing of sewers and burning of suspected dejecta.

Dr. Bruen referred to the importance of high arterial tension as a premonitory symptom of albuminuria. In therapeutics Dr. Bruen spoke favorably of antipyrin, finding temperature continued to fall for six hours after one or two doses. It depressed the heart and produced exhausting perspiration, though the former was less than that produced by others of the carbolic series. He used ten grains. Nitro-glycerine was valuable in lessening albuminuria associated with high arterial tension, but must be watched, as it might reduce it too far. Caffeine was a safe cardiac stimulant and diuretic, eight to ten grains daily. Hyoscine had been shown by Dr. H. C. Wood to be a safe and valuable spinal sedative. Dose, about $\frac{1}{100}$ of a grain.

DR. HENRY H. SMITH, Emeritus Professor of the University of Pennsylvania, read a paper on the

NON-CONTAGIOUSNESS OF CHOLERA.

The disease was known in China two thousand five hundred years before Christ.

Professor Smith had studied every epidemic in Philadelphia since 1832. All the physicians of repute at that time, such as Chapman, Horner, Hodge, Jackson, Condie, Coates, the elder Pepper, and Wood, were non-contagionists.

Horner demonstrated the desquamation of the epithelium of the small intestines in cholera, two years before Boehm claimed the discovery.

Dr. Smith, in the post-mortems, was frequently exposed six or eight hours to infection with impunity.

The Sisters of Charity, largely exposed, never suffered, yet often took typhus.

Mackintosh, of Edinburgh, reported that in hospital two hundred and eighty bodies were autopsied in a room eight feet square, with six or more persons present, none of whom were affected. He quoted Professor George B. Woods' argument against the contagiousness of cholera, and the report of Dr. Sterling, of New York City, 1849, of one hundred emigrants who arrived at quarantine in the ship New York, which had cholera on board, and who escaped from quarantine into adjacent towns without spreading the disease.

The question has been reopened by Koch's claim of a curved bacillus found only in choleraic discharges as the prime exciting cause. But it has never been verified by its producing the disease in man. Inoculation with comma bacilli as a preventive is proposed by Ferran, but his opinions are not assented to by M. Hericourt, of the French Academy of Sciences. (See THE MEDICAL RECORD, May 28, 1885, p. 586.)

The idea of a specific germ or bacterium is not new. Hahnemann ascribed the origin of most diseases to a microbe called Acarus.

Cowdell, of England (1848), assigns certain cryptogamous organisms, consisting principally of protein compounds, as in the protococcus nivalis, torula cervisæ, etc., as the cause of cholera; all of which have been found in the air and water of the vicinities of the disease and in cholera evacuations.

Professor J. K. Mitchell, of Philadelphia, advocated the influence of atmospheric spores in 1841.

Speaking of the various causes of cholera, Professor Smith referred to the use of alcoholic drinks, as quoted by Sir Wm. Gull, of London, who showed that the epidemic of 1848–49 had the largest average of deaths after payday.

Dr. Smith stated it would probably surprise many that while Koch claims to have discovered a "contagium

vivum," as the proximate cause of cholera he is unable to suggest any germicide that can be swallowed by man. Speaking in his address to the Imperial Board of Health of Berlin of the cry, "What is the use of this discovery to a practitioner?" Koch says, "You can deduce this advantage from it, that it will put an end to the fearful squandering of disinfectants, and that millions will not again, as in the last epidemic at Berlin, be poured into gutters and cesspools without the slightest advantage."

Dr. Smith closed by stating that, whether the contagiousness or non-contagiousness of cholera be admitted, it was important to the welfare of every community that all usual sanitary laws should be strictly enforced; he stated that if cholera should visit us this summer, it is not likely the epidemic will be so severe as those through which so many physicians have practised and lived without undue anxiety.

The venerable professor was listened to in respectful amazement by the votaries of the new etiology; the number and length of papers precluding discussion in this as in most cases throughout the session.

Dr. William F. Waugh, of Philadelphia, read a paper on

A NEW TREATMENT OF THE ALCOHOL HABIT.

The treatment of acute alcoholism is generally successful; but, except in a very few cases, the patient relapses into inebriety and dies a drunkard.

The disease, however, is not incurable. The causes of relapse are: 1, previous disease which led to drink; 2, overwork, especially when combined with illness; 3, gastric catarrh, due to alcohol; 4, catarrh of the mouth, due to the same cause; 5, depression consequent on withdrawal of the stimulant.

In the first and second classes the recognition of the cause affords the indication for treatment.

In the third class the remedies recommended are hot water with soda before meals; oxide of silver, oxide of zinc, or bismuth, following; and minute doses of ipecacuanha to restore the secretion of the digestive glands.

In the fourth and fifth classes the use of coca is recommended in the form of a masticatory, to obtain the local effect on the mouth, as well as the constitutional effect, in relieving the depression. The object is to substitute for the alcohol habit the harmless habit of chewing coca.

The food should be carefully regulated, and should at first consist of raw oysters, or beef with capsicum and vinegar, pickled tripe, or pigs' feet.

If the patient has passed the point when he still desires to be cured, and is unwilling to make an effort, he should be put under restraint, preferably in an institution where he could be compelled to earn his livelihood, instead of spending his time in enervating idleness.

Dr. S. M. Free, of Dagus Mines, read a paper on

MORPHIA IN CHOLERA INFANTUM,

reciting the failure of present plans of treatment, and the need of a better; he thought it could be found in the judicious use of morphia.

Few members coincided in his view of the propriety of using this potent drug in infancy.

A paper by Dr. Van Harlingen, of Philadelphia, was presented by title, on

DERMATITIS MEDICAMENTOSA (ERUPTIONS DUE TO THE INGESTION OF DRUGS),

showing that our knowledge of such drug eruptions has been much enlarged of late years; that certain drugs will almost invariably produce eruptions, while others produce them only in persons having a favorable idiosyncrasy. Medicinal eruptions have their diagnostic peculiarities; the nervous system is principally concerned in their manifestation. Their etiology and pathology invite investigation.

Dr. J. V. Shoemaker read a paper on

SOAPS ESPECIALLY MEDICATED IN DISEASES OF THE SKIN.

The value of potash soap medicated with tar, naphthol, carbolic acid, salicylic acid, sulphur, balsam of Peru, mercury, etc., was cited. Medicated soda soap has greater scope. It must be used judiciously once a day, or once or twice a week, according to toleration.

Alum soap, ten per cent., is useful in hyperidrosis and seborrhœa oleosa, and in excessive sudoriferous and sebaceous secretion. Many cases of pustular eczema, particularly in the subacute stage, are benefited. It should be used in lupus, cancer, and in scrofulous and syphilitic skin affections. It is stimulating and astringent to ulcers.

Arnica soap, ten per cent. extracti arnicæ, cures sore nipples, and is used about the mucous outlets of the body in cleansing boils, carbuncles, and pustular skin affections, in wounds and bruises of the integument. It is sedative to irritation, soreness, and pain.

Boro-glyceride soap, ten per cent. of a fifty per cent. solution boro-glyceride, is preferable to either borax or boracic acid soap; is antiseptic and deodorant; destroys germs. It is especially useful in pruritus. Valuable in acne and seborrhœa.

Camphor soap, ten per cent., is primarily stimulant, at times irritant, and secondarily anodyne. Used in the pruritus of eczema, chilblains, etc.

Carbolic acid soap is stimulant and anæsthetic; used for its antiseptic action in wounds, and in suppurating sores, relieving their accompanying itching. Chronic eczema, psoriasis, etc., are much benefited by it.

Chamomile soap, ten per cent. extract anthemidis, is excellent in intertrigo, dermatitis, seborrhœa, bromidrosis, etc. It is rendered more effective by the addition of sulphur five per cent.

Eucalyptol, naphthol, salicylic acid, and corrosive sublimate soaps, with some twenty other medicated soaps, were mentioned by the Doctor, who described their several uses, and cautioned that medicated soap is potent for harm if injudiciously used, disappointing if relied on exclusively, but is valuable as an adjuvant to other treatment.

Dr. T. Green said he would like to advise people

NOT TO USE CASTILE SOAP IN WINTER.

Dr. J. H. Packard read a paper on

TRACHEOTOMY.

The Doctor objected to tracheotomy-tubes, referring to Martin's proposal to dispense with them (Paper in "Trans. Am. Med. Asso.," 1878), and detailed his own attempts to dispense with them by substituting a wire frame or retractor; referred to hairpin and other retractors; the difficulty about lateral expansion; modification of the eye speculum for the purpose; Passavant's article; various forms proposed for trial and experiments on the dead subject; and concluded by saying that a perfect substitute for the tube was a desideratum, and crediting the elder Pancoast as the first to discard the tube.

Dr. Pancoast said that trachea-tubes were unnecessary and injurious. The trachea was itself a tube, and when incised the wound should be kept open without a descending internal tube.

Dr. H. H. Smith affirmed the position taken by the essayist, and said he had discarded the tube, with Pancoast, thirty years ago.

The Society, on invitation, visited the Lackawanna Hospital, and at 8 P.M. reassembled to hear the President's address.

The President, Dr. E. P. Allen, of Bradford County, delivered

THE ANNUAL ADDRESS.

Opening with reference to medical progress, he ran over the discovery of various anæsthetics up to cocaine; the mechanical inventions in instruments of diagnosis; microscopic discoveries of bacilli by Koch and others; diet;

massage and electricity in nervous diseases; the importance of Bigelow's advances in lithotripsy; Listerism; abdominal and uterine surgery. He spoke of the responsibility of the State Society in the matter of securing a State board of censors. The laws of the State recognize as a physician almost any person who advertises himself as such. The Doctor also spoke of the abuses of the advertising of the specialists, and closed his address by referring to the prospect of a cholera invasion, the apathy of the State and United States Governments in the emergency, and the importance of organizing local health boards. He doubted if our treatment of the disease would be more efficacious than in 1832 or 1854, and that prevention was the vital point.

THIRD DAY—FRIDAY, MAY 29th.

DR. C. M. WILSON read a paper on

MECHANICAL DILATATION OF THE UTERUS,

and exhibited a new instrument.

DR. WOOD, of Pittsburg, President-elect, read

THE ESSAY ON SURGERY.

He believed that the surgeon must have natural-born talent for the art, and deprecated the rush of incompetents into the profession. The time had come when selection must cull the fit and reject the unfit. The specialist who was nothing more was a traitor in the camp. His attacks were usually made on the eye, throat, or womb, while the true specialist was trained from the lowest round of the ladder of general medicine.

The special talent upon which he laid stress was the mechanical and geometrical.

Dr. Wood recommended the subcutaneous ligation of arteries, a common practice with Pittsburg surgeons, under the lead of Dr. Pollock, who believes it unnecessary to crush the arterial coats. Dr. Wood believed that the subcutaneous method should be exclusively employed for aneurism, using wire.

As the members whom we have consulted coincided with the essayist's views on "natural" talent, your correspondent appeals to you for sympathy in the view, that it is a great mistake to exalt this boyish tinkering with saws and little hatchets as premonitory symptoms of surgical talent.

Let the noble words of the worthy Doctor's former townsman, Andrew Carnegie, serve to say 'tis the same quality of mind—learning, judgment, and wisdom—with which "the enlightened *physician* gazes clear-eyed on the blazing sun of truth" and science, that will also best equip the surgeon.

DR. ADINELL HEWSON read a paper on

MORE RECENT EXPERIENCES WITH THE ELECTRIC LIGHT IN DIAGNOSIS,

and the topical uses of earth.

He takes a cone of binders' board, eleven inches long, the base used over both eyes; a finger held in the opening becomes translucent; the orifice has to be one-eighth by three-sixteenths of an inch.

Modification of star-lamp protected by an asbestos cap used, incited by three zinc carbon cells.

Every Tuesday women come to him with

NEEDLES IN FINGERS,

which he can see *in situ* through the flesh by this method.

Dr. Hewson was first led to use

EARTH AS AN ANTISEPTIC

in 1869; was led to determine the qualities of different earths. Clear yellow clay, free of sand or grit, was always used. With sixteen years' experience, the Doctor reiterates his claims for the utility of earth in erysipelas, measles, scarlatina, and small-pox, as well as in surgical cases. His more recent cases of measles and scarlatina have come in groups. In schools the earth not only produced great benefit, but prevented contagion on the return of the children to school, insured reduction of temperature, shortened the duration of the disease, and prevented complications.

He dusts the earth over the whole cutaneous surface, causing immediate reduction of five degrees Fahr. in early stage, and ten degrees when fully developed. In small-pox and erysipelas he mixes it with water to cause it to adhere—adding water raises temperature of clay for an hour. Allowing for this, it has always markedly reduced temperature (greatest in measles, ten degrees; next erysipelas, scarlatina, small-pox, five), in first twenty-four hours; in second twenty-four hours, not further reduced; in third twenty-four hours (greatest reduction in erysipelas), by end of fourth day, there is never abnormal temperature (except in small-pox or scarlet fever, perhaps two degrees, lasting till desquamation). The effect of moist clay on pain is very marked, the patient expressing relief during the dressing, and usually going to sleep. If there be pain in the chest in measles, apply clay to the chest.

February, 1873, prominent army officer, third day. Erysipelas of face and scalp, delirious, held by attendants; anodynes and stimulants had been freely used. They were withheld, and Doctor applied clay paste one-fourth to three-eighths of an inch over the whole face; before dressing was completed, relief and sleep occurred, lasting from midnight until 4.30, when already the face was much shrunken. Dressing reapplied, improved rapidly, and cured in a week.

Case of small-pox, ten years ago; prominent lawyer; discrete eruption on face and spreading; had never been vaccinated. Patient proposed to use the clay on one side of the face (after days' consideration and probably advice) and French devize plaster on the other. Applied clay on right, plaster on left, both ears left uncovereed the right side was exposed to greater light. Applid; plaster accurately, made clay one-fourth inch thick, except over eyelids, half an inch. Patient said the earth was more comfortable, and next morning asked to have it on both sides. The right side shrank markedly, and its temperature fell five degrees, while no such effects occurred on the left until the ninth day. On removal no pitting or discoloration; whereas, on the left, pitting was abundant and surface looked like a burn. The contrast was very striking.

On motion of DR. WOOD, the resolution of last year, forbidding the publication of full papers, was rescinded.

The report of committee by chairman, DR. SHAKESPEARE, considering the act recommended by American Medical Society for State Board of Censors, was favorable.

DR. COHEN stated a report was due the American Medical Association.

DR. ROBERTS suggested that the Secretary should report to American Medical Association, that the act was read and referred, and that the Society had yesterday embodied similar bill and referred to committee to report. Adopted.

Resolution laid over for action next year, to make a medical journal of the State an official journal.

A paper by DR. BENJAMIN LEE, of Philadelphia, was entitled

NIL DESPERANDUM IN SPINAL CARIES.

The Doctor said it was never too early to employ mechanical support, and *never too late*. Expectant treatment was a blunder.

Diagnosis was easy long before deformity. Sudden cramping pain in the abdomen and sides, stiffness in walking in the morning, inability to stoop forward and touch the floor, "toeing in," and holding the shoulders high and stiff. If an infant, it will scream on being moved and lifted. There was not generally pain or ten-

derness in the back, and it was a great mistake to pronounce that there is nothing the matter with the spine because that symptom was absent. The disease often follows whooping-cough, and very often can be traced to a fall or other injury.

It *was never too late*, and it is a great error to suppose that strength was necessary to bear a surgical apparatus; when local irritation was wasting the vital energies, mechanical support was the best tonic, without which medication was vain. The doctor cited a case of a boy, six years of age, with cervical caries following whooping-cough two years before; complete paralysis; wasted to a skeleton; racking cough.

The brace gave immediate relief, and in a week he slept and ate well, and could move two fingers; and in two weeks his toes and arms. In five months he could walk alone.

Dr. H. R. Wharton, of Philadelphia, read a paper on

OSTEOTOMY FOR THE CORRECTION OF DEFORMITIES IN THE LOWER EXTREMITIES,

in which he gave preference to the linear operation over the cuneiform, as it consists of a simple section of the bone and practically constitutes a subcutaneous operation, whereas the latter, in which a wedge of bone is removed, necessitates an open wound with its attending dangers.

The use of the osteotome or the saw rests with the operator.

The importance of making a full correction at the time of operation is insisted on, especially if a fixed dressing is to be afterward employed.

Among the causes which produce deformities, for which osteotomy may be required, are those arising from rachitis, from coxalgia, from badly united fractures, or from reduced dislocation; and of all these the vast majority of cases requiring the operation are due to the first-named cause.

For the correction of angular deformities at the hip-joint resulting from coxalgia, Gant's modification of Adams' operation is preferred; that is, a section of the femur just below the lesser trochanter. This operation is preferred because section of the bone at this point secures its division at a locality where its structure is comparatively healthy, whereas its division through the diseased strictures of the neck, if it still exists, is capable of renewing an active inflammation in tissues which are most susceptible to inflammatory accidents following traumatism; also from the fact that the femoral shaft can no longer be influenced by the action of the psoas magnus and iliacus muscles. The chances of recurrent deformity are less when the section is made at this situation. Adams' saw was, for the author, a most satisfactory instrument, although others express equal favor for the osteotome.

In a large number of cases he has had no fatal result.

For genu valgum he prefers MacEwen's operation—linear section of the femur made from the inner side of the thigh, with the osteotome, just above the epiphyseal line.

For knee anchylosis he prefers Mr. Barwell's linear section of the femur just above the joint, with section of the tibia through its tubercle.

In genu varum a linear section of the tibia, fibula, and femur, with an osteotome at the point of greatest curvature, has been found a safe and efficient means of correction.

In tibial curves a linear osteotomy at the point of greatest curvature, or in aggravated cases a number of linear osteotomies, or the removal of a wedge of bone may be required.

Plaster-of-Paris dressing is strongly recommended.

Dr. D. W. Kearns, of Pittsburg, read a paper on

"RETROFLEXED SPLINTS FOR FRACTURE OF THE FOREARM,

especially Collis' fracture," with drawings and samples.

The point made was that the hand should be maintained in partial extension with the forearm to

RELAX THE EXTENSORS!

Dr. Packard challenged the principle.

Drs. Pollock, Roberts, Green, and others discussed the matter. The country doctors listened silently, thinking that the use of fancy splints was unnecessary in these fractures.

The visitors, by the courtesy of Superintendent Hallsted, of the Delaware, Lackawanna & Western Railroad, visited the mines.

THE NEXT ANNUAL SESSION

will be held in Williamsport on the first Wednesday in June, 1886.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MALE NURSES FOR MALE PATIENTS—THE COLLEGE OF SURGEONS—CHOLERA—THE TEMPERANCE HOSPITAL.

London, May 23, 1885.

A scheme is now afoot in London for providing a corps of trained male nurses for hospital and private use. The claims of women to have medical attendants of their own sex have been urged for years, and many medical men have warmly supported their cause. After many struggles, the London School of Medicine for Women is now an accomplished success, and as two licensing bodies have opened their examinations to women, several of the alumni of the London School are now in practice. One of these bodies is the "Kings and Queens College of Physicians," in Ireland; the other is the University of London.

The admission of women to the medical and other examinations of the London University was largely due to the indefatigable exertions of the late Dr. Billing, F.R.S., Consulting Physician to the London Hospital, and one of the original members of the Senate of the University of London. Medical men have also of late years done a good deal to promote the training of midwives. In fact, many members of the profession wish to see the attendance of all ordinary cases of labor taken out of the hands of medical men altogether.

It has, however, been reserved for a lady to propound a scheme for supplying sick men with trained nurses of their own sex. The lady in question is Miss Jane Hamilton, a sister-in-law of the late Dr. Billing. Although advanced in years, Miss Hamilton has taken up the matter warmly, having had her attention drawn to it by the discomforts experienced by gentlemen of her own family and friends in being obliged to have female attendants in time of sickness. Several cases came under her notice, of single gentlemen living in chambers, who, being ill, were obliged, at great inconvenience, to have women-nurses to attend on them after the performance of operations. A great deal has been said about the indelicacy of medical men attending upon sick persons of the other sex. No one hitherto has made any protest against a sick man having a nurse of the opposite sex to wait upon him. The relations of nurse and patient are, however, much more intimate and continuous than those of doctor and patient. Many people object to man midwives. What would be thought of a doctor who suggested the employment of a male monthly nurse?

An association has already been formed to carry into effect Miss Hamilton's scheme. It is proposed to establish a training-school for male nurses in connection with one of the metropolitan hospitals. Communications have already been opened with one of the largest of these institutions. The preliminary inquiries which have already been made have revealed the undoubted ex-

istence of a want for trained male attendants in time of sickness. I happen to know that a large number of army surgeons are thoroughly convinced that the system of female nursing which has of late years found its way into the army has proved itself an unmixed evil. In active service this is especially the case. Women have been found to be totally unfit for the scenes of the battle-field.

The terrible sights they are forced to see, and the part they take in closely tending men of all ages with wounds of all kinds—some of them of a delicate nature—tend also greatly to blunt their modesty and delicacy. They are too comparatively alone among numbers of the opposite sex. Some surgeons even go so far as to say that women tend to become immodest under such circumstances. It has, at any rate, in some continental States, been found necessary to issue the most strict regulations respecting the attendance of soldiers by female nurses. The effect, too, on the wounded men is bad. The opinion has been recorded, by an able American army surgeon, that the presence of a young woman among wounded soldiers is detrimental, by keeping them in a continual state of sexual excitement. The old system of regimental orderlies was far preferable in the opinion of army men.

A good deal of what I have just stated is equally applicable to civil life. Modesty is not the sole monopoly of women, and there are certain cases in which the aid of a male attendant would certainly be more decorous, and also more acceptable to the patient. Miss Hamilton's scheme is only just launched, but considerable support is already promised, and no inconsiderable amount of funds has already been guaranteed. A primary object of the founder is the provision of male nurses for cases in private practice, but it is also hoped that the hospitals will take up the matter, and that in time the employment of men as nurses in the male wards may be in future the rule—not the exception. Men-nurses have already been tried on a small scale in workhouse infirmaries, and, so far, have proved a success.

The Fellows have finally agreed to make common cause with the Members against the Council of the College of Surgeons. They have at last recognized the claim of the Members to representation, and have agreed that the latter shall elect one-third of the members of the Council, but no Member is to have a vote until he has been a Member for ten years. The remaining two-thirds of the Council are to be elected by the Fellows as before. The Members will, no doubt, agree to meet the Fellows, by accepting this concession, though their original claim was that they should elect half the Council.

There are indications that we are on the eve of a cholera scare. During the week the papers have reported the outbreak of cholera at Marseilles, and circulated an entirely unfounded report that cases had occurred at Durham. Dr. Sanderson has been lecturing on the subject at the Royal Institution, and declared that if an epidemic broke out in East London the inhabitants of the North and West need have no fear of it, and he stated that if the disease were to reach London this year it ought long ago to have been on the march. In connection with this, I may remark that public attention has also been greatly excited by the proposal of Dr. Ferran to vaccinate for cholera, and the results he has achieved in Spain, Dr. Cameron, M.P., having introduced the subject in Parliament, and published the statistics supplied him by Dr. Ferran.

Last Saturday a Grand National Bazaar was opened by the Duchess of Westminster, in order to defray the cost of a new wing to the London Temperance Hospital, which has just been completed, and raises the number of beds to one hundred and twenty. There is no doubt the money will be raised, one gentleman having given five thousand pounds, which is more than half the sum required. This hospital was opened twelve years ago, for the treatment of all medical and surgical cases without the administration of alcohol in ordinary cases. The physicians and surgeons were not, however, debarred from giving it in any case which seemed to require it. When prescribed, a record was to be made of the circumstances, the dose given, and the apparent effect. This permission they have only availed themselves of in a few cases, and in none did they consider the alcohol did good.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE TEMPERATURE OF THE HUMAN BODY—ETIOLOGY OF ERYSIPELAS—DR. FERRAN AND THE INOCULATION OF THE COMMA BACILLUS—CHOLERA IN VALENCIA—EXPERIMENTS OF DR. ROCHEFONTAINE.

PARIS, May 20, 1885.

DR. CHARLES RICHET lately presented a paper to the Academy of Sciences on the temperature of the human body in a state of health, which may be summarized as follows: The minimum of the body temperature presents itself nearly always at the same hour, about three, four, or five o'clock in the morning, and the maximum about three, four, or five in the afternoon. During the night, from the moment that one gets into bed until he wakes in the morning, the temperature is lowered; in the morning it rises slowly. This rising increases after the repast and reaches the maximum about four o'clock in the afternoon, owing to the general nervous activity that manifests itself during the day. The lowering of the temperature commences in the evening; in spite of the evening repast, it pronounces itself more and more, and goes on increasing until three in the morning. In fine, the temperature, whether deep-seated or superficial, varies between 36° and 38° C. Should other degrees of temperature be noticed, at least in these climes, the organism is not altogether in its normal condition. Such is the general course of the body temperature in health. There are, however, certain exceptions to this rule, and it has been observed that the difference of the diurnal and the nocturnal temperature has been completely reversed. For instance, in bakers, miners—in short, in all people who work at night—when the periods of muscular activity and of rest are interverted, their minimum and maximum temperature are also interverted.

At the recent debates at the Academy of Medicine on the etiology of erysipelas, some of the members admitted the existence of a contagious or infectious principle, in the form of a virus or germ, which caused the disease, but the nature of the virus was left undetermined. Professor Cornil, the well-known histologist, in undertaking to search for the microbe of erysipelas, found a streptococcus resembling very much that of phlegmon, but differing from the latter in that, when inoculated, it always reproduces erysipelas. This remarkable fact is, according to the author, sufficient to affirm the existence of this micro-organism in erysipelas, in which it clearly stands in the relation of cause and effect. These microbes are of a round shape, and are found generally associated in pairs or in sinuous chains in the cutaneous tissue, in the lymphatic vessels, in the adipose cells of the skin, and of the subcutaneous cellular tissue. These micro-organisms are sometimes conveyed along the general circulation, and are excreted by the urine. They are also found in the lungs affected with congestion or inflammation, as well as in inflamed meninges. The same microbes are constantly met with in the urine of albuminuric patients affected with erysipelas, and when these patients die from albuminous nephritis, the vessels of the kidney are filled with them. Whether the erysipelas be mild or severe, spontaneous or surgical, these micro-organisms are always to be met with in this affection, and are always arranged in the same fashion. This microbe can be cultivated in gelatine, and inoculation from this culture gives rise to a simple erysipelatous erythema, without producing any severe accidents. The parasite of erysipelas

may therefore be generally considered but little dangerous, and if the disease proves fatal in certain cases, as in patients operated on, lying-in women, M. Cornil thinks that it is because the organism is not, in these cases, in a normal condition; also because these micro-organisms are found mingled, at the moment when the contagion is effected, with those of suppuration and of puerperal fever. The variations of degree of the severity of erysipelas may be explained by the addition of other bacteria to those which are spécial to this malady. In this category may be included the eruptions which succeed certain cases of traumatism. These facts made Professor Trélat remark that the researches of M. Cornil are of the highest importance, and it may now be understood why it is that certain forms of dressing are better adapted to combat the pyogenic organisms, and certain others to combat the erysipelatous organisms.

In my last, I brought to notice a process proposed by Dr. Ferran, of Tortosa, for the attenuation of the virulent effects of cholera by the inoculation of the comma bacilli, to which he has given the name of cholerization. Dr. Ferran has had an opportunity of putting this method to the test, and he has announced that, during the recent epidemic of cholera in the province of Valencia 4,700 persons got themselves inoculated as a precautionary measure against the disease. Of this number, five only were affected by the disease, but none of them died. Dr. Ferran, encouraged by this result, has expressed his intention to proceed to the other infected provinces there to apply his method, after which he intends visiting France and England, where he will prosecute his ideas and perform further experiments.

Since the above announcement, intelligence has been received of the reappearance of cholera in the province of Valencia, which may probably alter Dr. Ferran's intention of leaving Spain for the present. Every precautionary measure, such as isolation and disinfection, is being taken to prevent the spread of the disease.

It may be well here to recall the experiments of Dr. Rochefontaine, which were reported by the Paris correspondent of the *Lancet* of the 9th inst., by which it will be seen that the introduction into the system, by the stomach or by hypodermic injection, of cholera microbes, was attended with negative results, at least in so far as concerns the reproduction of the disease. It is, therefore, difficult to conceive in what way Dr. Ferran's method of cholerization would act as a prophylactic.

ON THE PRELIMINARY REPORT OF THE COMMITTEE ON DISINFECTANTS OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

To the Editor of The Medical Record.

Sir: This report, coming from a committee the members of which are well known in connection with sanitary science, will no doubt receive the careful attention of both the profession and the public, and the recommendations contained in it accepted as the best possible in the present uncertain state of this science. That this is true of a majority of them no one is likely to question, but a few of them are of such a nature that one cannot help thinking that they are not based on experiment, but on theoretical reasons. In calling attention to these there is no desire whatever to cast doubt on the report as a whole, or on the experimental work on which the greater part is based, but merely to bring before the Committee such points as require attention and probably change in issuing their final report. These are not questions of difference of opinion, but errors, chiefly of a chemical nature, that have in some way escaped the notice of the two chemists on the Committee.

One of the most conspicuous of these is the recommendation of a "disinfecting and antiseptic powder" consisting of one ounce of mercuric chloride, one pound of bleaching powder, and nine pounds of plaster-of-Paris. The following directions are given for use:

"To disinfect excreta in the sick-room, cover the entire surface with a thin layer of the powder—one-fourth inch in thickness—and if the material is not liquid, pour on sufficient water to cover it."

In the first place, the mercury in this mixture is precipitated by the lime present as mercuric oxide, which is practically insoluble, and has little or no germicide or antiseptic action. The second objection to its use is probably even more serious than this. The plaster-of-Paris will in a few minutes set to a hard mass, forming a wall around the "germs," but rather inconvenient to remove from vessels, waste-pipes, etc.

The next recommendation is rather more remarkable than the above; it is as follows:

"Standard Solution No. 4. Dissolve corrosive sublimate in water in the proportion of four ounces to the gallon, and add one drachm of permanganate of potash to each gallon to give color to the solution.

"One fluid ounce of this standard solution to the gallon of water will make a suitable solution for the disinfection of clothing. The articles to be disinfected must be thoroughly soaked with the disinfecting solution and left in it for at least two hours, after which they may be wrung out and sent to the wash."

We would suggest burning the clothing as preferable to this treatment, for when they are taken out of this solution they will be of a dark-yellow color from the deposit in the fibre of manganese dioxide, which can be removed only by treatment with a strong acid. It may seem that the dilution of the permanganate is too great to accomplish this, but the above statement is based on actual experiment with the solution recommended.

The following directions for disinfecting rooms are in keeping with the above:

"All surfaces should be thoroughly washed with a solution of corrosive sublimate of the strength of one part in one thousand parts of water, which may be conveniently made by adding four ounces of Standard Solution No. 4 to the gallon, or one pint to four gallons of water. The walls and ceilings, if plastered, should be white-washed with a lime-wash containing the same proportion of corrosive sublimate, or they may be brushed over with the aqueous solution."

Of course, Standard Solution No. 4 would color walls the same as it would clothing, especially as in this case it is to be diluted only one-fourth as much, while adding corrosive sublimate to lime would precipitate the inert mercuric oxide. Even in case the aqueous solution was used, the lime in the plaster would perhaps produce the same effect, while, if it did not, the propriety of saturating the walls of apartments with corrosive sublimate is doubtful, since the much less volatile arsenic compounds are known to be deleterious when applied to wall-papers.

For the disinfection of excreta—not previously disinfected—of patients with cholera or typhoid fever, after it has been thrown into privy-vaults, the Committee recommend, among other agents, the use of one pound of corrosive sublimate to every five hundred pounds—estimated—of fecal matter. It is true that, according to most authorities, a one to five hundred solution of corrosive sublimate is an efficient disinfectant, but it must be remembered that we have here entirely different conditions. Even if the thorough diffusion of this salt through the mass of semi-solid matter was possible, it is doubtful if it would act in the presence of such a proportion of organic matter; but everyone knows how slowly mercuric chloride dissolves, even in a large excess of water, while in such a mass of fecal matter every particle of it would probably become encysted in an envelope of the insoluble albuminate, and remain so indefinitely. In fact, it is extremely probable that but little more would be accomplished by this treatment than by dropping a burning sulphur match into the vault.

The statement of the report, that chloride of lime is, perhaps, entitled to the first place for disinfecting excreta, on account of the rapidity of its action, is misleading, since sodium hypochlorite is equally rapid in its action, and it also possesses certain advantages over the calcium salt not mentioned in the report.[1]

The Committee assume that the Labarraque's solution (liq. sodæ chlorinatæ) used will contain at least three per cent. of available chlorine, but none of the officinal solutions in the market contains this amount. We understand, however, that a standard solution of this strength is being manufactured.

In speaking of the solution of mercuric chloride and potassium permanganate (1 to 500 of each) the report states that this is equally as efficient as the hypochlorite solution for the disinfection of excreta, vomited matters, sputum, etc. This is scarcely in accord with the following, which is from a very recent article by the Chairman of the Committee, and one of several on which the present report is based :

"In a previous paper (*The Medical News*, January 10, 1885, p. 34) the writer has recommended the use of a solution containing 1.500 of mercuric chloride, and 1.500 of potassium permanganate, as an efficient disinfectant for sputum and for the discharges of patients with typhoid fever and cholera. The experiments of Schill and Fischer, which I had not read when this recommendation was made, indicate that it will be necessary to use some other agent when the object in view is to destroy the infective virulence of tuberculous sputum. And, in general, it will no doubt be better to use an oxidizing disinfectant, such as the hypochlorite of soda, when the germs to be destroyed are embedded in masses of albuminous material. For such masses are disintegrated and destroyed by oxidizing agents, whereas corrosive sublimate has the opposite effect, in consequence of its power of combining with and coagulating albuminous material" (*The Medical News*, February 21, 1885, p. 208).

In conclusion, we regret to be obliged to call attention to these evidences of hasty preparation, which was not to be expected of so able a committee, and of the many and valuable experiments on which the greater part of it is based. The agents recommended, however, are undoubtedly the best at our command, and notwithstanding what has been mentioned, the report contains much that is valuable, and is calculated to correct some of the fallacies on disinfection.

Very respectfully yours,

Delirium Tremens in a Boy Three Years Old.—Dr. A. W. Benton, of Neosho, Mo., writes : "On April 29th, at 1 P.M., I was summoned to see a mulatto boy aged three years and five months. Parents stated he had obtained one half-pint of whiskey, and drank nearly all of it between 6 and 7 that morning, sleeping so soundly they could not wake him. An emetic and warm bath aroused him, and he seemed to be all right but a little stupid. I took my departure after leaving directions for his care, and was soon summoned again, the father telling me the boy 'had fits.' Arriving, I found a marked case of delirium tremens, the child fighting imaginary animals, quieting down in a few minutes only to begin again with terrific screams and struggles, making at the same time most piteous appeals to those around for protection from his tormentors. Under the influence of chloral and bromides the symptoms gradually subsided, leaving but a faint trace of trouble the following morning. This is the youngest patient suffering from alcoholism I have ever seen or heard of."

Is Death from Heart-wounds Instantaneous ?—Dr. T. O. Reynolds, of Kingston, N. H., writes : "The article in The Medical Record of May 9, 1885, by Dr. Pettit, narrating the case of Bessey, who was shot with 'B.B.'s,' and on examination was found to have received a wound of the heart, but on evidence was found to have lived long enough to perform locomotion to the distance of eight feet, calls up to my mind a case in point which occurred at Camp Nelson, Ky., in 1864, during my service there in the Convalescent Hospital. On the Nicholasville turnpike, which ran directly through the camp, had gathered sutlers and other enthusiasts, civilians, who sought to serve their country by acquiring rapidly a competency out of the boys in blue. Among these was one, a 'jeweller,' etc., who had erected a temporary dwelling and shop. He was prone to intoxication, and personal belligerency when in that state. One evening he gave a party, and many of the 'boys' were invited. I was among the number present, and we were enjoying a most pleasing evening. Late in the evening, it was remembered that Mr. —— was absent, and presently he came rushing frantically into the presence of all, covered with blood, flourishing a dagger, and exclaiming, in a manner which showed him to be drunk, 'I've done it, I've done it,' etc., etc. We rushed out to see what diabolical act had been enacted, and found two of our comrades, one dead, the other very severely wounded. The wounded soldier was at once conveyed to Ward 2, and cared for. He had several dagger wounds, one of which, it was feared, might prove fatal, being between the ribs

and over the heart. It was not deemed prudent to probe this, so it was simply dressed and the patient made comfortable for the night. He lived until the *second day following*. An autopsy revealed, to the astonishment of all, that the wound feared had penetrated the pericardium and punctured the anterior wall of the heart itself, over the septum, making a wound in the muscular wall one half-inch deep and as long. I was at the time chief clerk of the hospital, and was present at the autopsy, and well remember the circumstances and wound in the heart-wall. The cavities were not, of course, entered by the dagger; but there was a wound of the heart, and the patient lived thirty-four or thirty-six hours. Being myself a medical student at the time, I was, of course, specially interested in the case, and its every point of interest to us then remains vivid with me now. I think the case was reported to the Surgeon-General's office."

Passage of a Tooth-plate through the Pylorus.—Referring to a recent remark of our Vienna correspondent, that Prof. Billroth had "never known of an object the size and shape of a plate with teeth passing the pylorus," Dr. C. H. Hunter, of Minneapolis, sends us the following: "About a year ago, a man came to me with a plate carrying two teeth lodged in the œsophagus, opposite the thyroid cartilage. Several unsuccessful efforts to remove it with forceps and probang were made. He was given ether, with a view of opening the œsophagus. After a few whiffs, the patient sprang suddenly to his feet, and exclaimed, 'I've swallowed it!' Three days thereafter (six after the accident) the teeth and plate were passed by the rectum unchanged."

The same gentleman also writes: "Apropos of wounds of the heart, remarked upon editorially in a recent number of The Record, a case in point was discovered not long since by the coroner of our city. An unknown man was shot in the chest at close quarters. He walked from the rear to the front of the house—sixty feet, up a flight of stairs, back to a rear window, threw up the window, called out, and fell back dead. The bullet, 32 (?) calibre, it was found, had passed through both ventricles."

Why Women Physicians Tend to Homœopathy and Quackery.—Dr. R. O. Geroke, of Augusta, Ga., believes that he has discovered why a large number of women physicians turn out quacks. It is due to the natural peculiarities of the female mind and character, which peculiarities were, he says, correctly and acutely set forth by Swedenborg one hundred and fifty years ago. Says this author: "There are duties proper to the husband, and others proper to the wife. . . . The wife cannot enter into the duties proper to the husband, nor, on the other hand, the husband into the duties proper to the wife, because they differ like wisdom and the love thereof, or like thought and the affection thereof, or like understanding and the will thereof. In the duties proper to husbands, the primary agent is understanding, thought, and wisdom; whereas, in the duties proper to wives, the primary agent is will, affection, and love. . . . Many believe that women can perform the duties of men, if they are initiated therein at an early age, as boys are. They may, indeed, be initiated into the practice of such duties, but not into the judgment on which the propriety of duties interiorly depends; wherefore such women as have been initiated into the duties of men, are bound, in matters of judgment, to consult men, and then, if they are left to their own disposal, they select from the counsels of men that which suits their own inclination. Some also suppose that women are equally capable with men in elevating their intellectual vision, and into the same sphere of light, and of viewing things with the same depth, and they have been led into this opinion by the writings of certain learned authoresses; but these writings, when examined in the spiritual world in the presence of the authoresses, were found to be the productions, not of judgment and wisdom, but of ingenuity and wit; and what proceeds from these, on account of the elegance and neatness of the style in which it is written, has the appearance of sublimity and erudition; yet only in the eyes of those who dignify all ingenuity by the name of wisdom." It might be objected to the above that Swedenborg did not bear in mind the fact, for example, that there are forty thousand old maids in Massachusetts to whom "the duties proper to a wife" are not known. It has also been learnedly argued that medicine does not require an elevated intellectual vision, and hence may be practised by women.

Man as a Chandelier.—Sir William Gull relates the following: "While I was resident physician at Guy's, a drayman of intemperate habits was admitted by me into Lazarus ward, at about nine o'clock in the evening. He was suffering under extreme difficulty of breathing, great distention of the venous system, and other symptoms of dilatation and obstruction of the heart. A large, fat, bloated man with purple face. He died within an hour or so of his admission into the hospital. The following day, at one o'clock, the weather being cool, the body was placed on the table for a post-mortem examination. There were no signs of ordinary decomposition, such as would account for the remarkably distended condition of the whole body. The skin and parts beneath were throughout distended with gas. In the absence of signs of decomposition, and from the shortness of the time since death, it was suspected that this gas must have been exhaled from the blood, and was of no ordinary septic character. When punctures were made into the skin, and a lighted match applied, the gas which escaped burnt with the ordinary flame of carburetted hydrogen. So many as a dozen of these small flames were burning at the same time over the distended body."

Peptones à la Mode.—A French health journal relates a pleasing little tale of a man whose movements attracted the attention of a detective. He was noticed walking through the streets with his eyes fixed intently on the ground, occasionally stooping to pick up something which he put in a basket. The detective ascertained that he was collecting canine excrement, and being curious to know what he did with it, followed him, and saw him enter a manufactory of peptones and beef-extracts. Subsequent investigation revealed the fact that the excrement was mixed with beef-powder and sold as a superior article of peptones.

Secretion of Milk in a Nullipara.—Dr. Mascarel related to the Medico-Legal Society of France the case of a married woman, thirty-five years of age, who had always menstruated regularly and had never been pregnant. For the past six years the mammary glands had been secreting milk. They were of rather small size and marked with numerous veins, but there was no brown coloration of the areola. There was no uterine disease. —*Giornale Internazionale delle Scienze Mediche*, No. 4, 1885.

Italian Medical Congress.—The eleventh congress of the Italian Medical Association will be held at Perugia in November of the present year. The last Congress of the Society was held at Modena in 1883.

The Local Application of Caffeine to the Conjunctiva.—Dr. Argyll was led, by the chemical relationship between cocaine and caffeine, to make a trial of the latter as a local anæsthetic to the conjunctiva. He employed a solution of sixteen per cent., instilling one or two drops into the eye. Dilatation of the pupil occurred in from ten to fifteen minutes, but no anæsthetic effect was produced. —*Revista de las Ciencias Médicas.*

Another Projected Medical Congress.—It is proposed to hold an international exposition in Barcelona at an early date, and our Spanish contemporaries suggest that a congress of physicians be held there at the same time.

Original Articles.

CLINICAL REPORT OF TWO SETS OF CASES OF FRIEDREICH'S DISEASE (HEREDITARY OR FAMILY ATAXIA).

BY E. C. SEGUIN, M.D.,

NEW YORK.

PERHAPS no excuse is required in presenting a merely clinical report of these cases. Their absolute rarity is a sufficient reason for placing them on record as they are, with the hope that in time we shall have light upon their pathological anatomy and etiology. An excellent digest of the subject, with summaries of all cases, including seven in which autopsies were made, is to be found in *Brain*, 1884, p. 105. It is from the pen of Dr. J. A. Ormerod.

It has been my fortune to meet with two families in which this disease occurred, and I have been able to examine five out of the six patients. In neither of these families was the affection, or indeed any nervous affection, hereditary; it was a family disease. In none of the cases could any ætiological factors be determined.

FIRST FAMILY.—K——, of the town of B., in New Jersey. Three cases. In the autumn of 1877 two children of this family were brought to me for consultation by their physician, Dr. S. S. Clark. The third child was examined at his home a few days ago, when I also had the opportunity of re-examining one of the other cases. The third case, a boy seen in 1877, died in 1883, and through a mischance no autopsy was held.

Family history.—Parents and grandparents remarkably healthy. The mother died in child-bed in 1878 or 1879. No neurotic taint except migraine in the father. Six children born. Of these one died at the age of seventeen months; one son and two daughters developed the ataxic disease; and two, a son, aged twenty, and a daughter, aged eighteen, remain healthy.

CASE I.—Lizzie K——, seen October 29, 1877, aged eighteen; was born perfectly normal; walked at ten months. From age of four or five years ankles began to show weakness—an increasing weakness. In the last three years (from fifteenth year) hands have become weak; writing and all small movements difficult. The back is not weak, and she can rise easily from sitting posture on a chair. Patient says she feels as if greatest weakness were at the hips. At times she stumbles. Sometimes, after sitting awhile, she has jerking movements of the legs; also cramps in the feet. No numbness or sharp pains. No difficulty in speech, and indeed no cerebral symptoms. Bladder acts well, but there is marked constipation.

Examination.—Healthy, rosy-cheeked girl. Walk is waddling and ataxic, with flat feet; closing eyes causes increased staggering and renders standing almost impossible. Ataxia of upper extremities is very marked, especially in the right hand. Yet patient has a good grasp, and she has observed that she could do things requiring strength better than those requiring skill. No muscular atrophy or loss of musculo-faradic reaction. Sensibility is normal. Reflex from soles increased (patellar reflex not noted). Ophthalmoscopic examination negative.

Second set of notes taken June 5, 1885, at the patient's home: When Lizzie was fourteen years old (four years before I saw her), she was brought to New York to consult a prominent surgeon, who ordered her "braces" somewhat different from the apparatus she had already tried. She also had a course of "movement cure," extending over several months, without relief. The awkwardness and weakness steadily progressed. In the last three years she has been unable to walk or stand; passes her time in a wheel-chair. Handwriting difficult and awkward from an early age; holds the pen with an abnormal effort. Speech affected in the last few years; hurried and jerky; tone of voice uncertain, quavering, very much as from partial paralysis of the vocal cords. Articulation not syllabic. Occasionally chokes while eating. Never diplopia. Never numbness or sharp pains in legs. Occasionally has cramps in calves, especially in early morning. Much troubled by chilblains in last two winters. Often has large jerking movements of legs upward while sitting. Feeds and dresses herself, though awkwardly, and is able to sew and do "fancy-work." Mental development good, though limited for age; in fact, the patient's manner and appearance are more like those of a child of twelve or fourteen years than like those of a woman of twenty-six (her present age). At times she is obstinate; insists upon doing all she can for herself. No hysteria. Moral nature well developed; has a kind and cheerful disposition. Takes pleasure in sending flowers and clothing made by herself to charitable institutions. General health excellent; menses regular.

Examination.—Sits rather limp and lolling in her wheel-chair, but she can sit up straight for a few moments; revealing a scoliosis to the left in the dorso-lumbar region, with abnormal anterior bend of spine between the shoulders.

Eye muscles and pupils normal (ophthalmoscope not used). Tongue not fibrillary or ataxic, points to the right; can purse lips well. Voice quavering; articulation jerky, but not syllabic.

Grasp good; R., 21°; L., 22°, on a stiff dynamometer. In act of grasping carpi are over-extended. There is typical ataxia of both arms, increased by closing eyes. The ataxia consists of rather large oscillations (inharmonious action of antagonistic muscles), without tremor. In holding arms and hands extended before her there is over-extension and separation of the fingers, but no tremor.

She cannot stand. Feet cold, bluish, and deformed; hollow sole, toes over-extended (especially the great toe), the heel somewhat drawn up, and tendo Achillis tense—a pes equino-varus. The calves are small, but there is no muscular atrophy, strictly speaking. The legs show no tremor, and even to the pin-test hardly any ataxia. She extends the leg quite fully and steadily with help of sight. Sensibility on face, hands, and legs is normal, except that distance of perception of æsthesiometer points is rather large. No positive anæsthesia, and no retardation of transmission.

Reflex from soles very much exaggerated. Patellar reflex absent.

In acts of drinking and writing there is a slight rhythmical lateral oscillation of the neck and head. This is the only tremor exhibited by the patient.

CASE II.—L. K——, aged fifteen years when seen by me, November 14, 1877. Died in 1883. My old notes simply state that the history and results of examination were the same as in his sister's case. Symptoms less advanced.

Second history obtained from Dr. Clark and the parents June 5, 1885: L—— was an unusually bright and

healthy boy, of studious habits and quiet ways. At the age of ten to twelve years it was noticed that his walk was not normal. He walked in an irregular, oscillating manner. There was no paralytic attack, but the symptoms came on insidiously, and progressed until death. Before 1877 he occasionally fell. Some time after the consultation the arms became affected, and speech became slow and a little thick (apparently never syllabic). Toward the end of life chewing and swallowing were difficult. He was able to read print to the last, and there was no nystagmus or squint. No numbness was complained of, and Dr. Clark never observed anæsthesia. He never had sharp pains. For a year or more before his death, L——, as he sat in his chair, held his head strongly backward, face up, as if the posterior cervical muscles were weak. Toward the last he was much doubled over forward in a sitting posture.

When quiet he had no tremor or jerking, except occasionally a sudden upward jerking of the legs while seated (as in Case I.). There was extreme ataxia of the upper extremities, and before replying to questions there were large choreiform movements of head, arms, and trunk. He retained power of motion in the legs to the last, although they were much wasted, much more so than the arms. There never was rigidity. During the last two months of his life L—— was practically insane—violent, destructive, and having paroxysms of screaming in which he was hardly conscious. He was also silly, which was in great contrast to his previous state.

Dr. Clark, from an early period, noted complete absence of patellar tendon reflex.

Death occurred from simple asthenia. The parents desired an autopsy, but owing to the absence of Dr. Mitchell (who had also seen the cases) and myself, it was not done.

Case III.—N. K——, aged fifteen years. Seen June 5, 1885. This patient was taken to Dr. S. Weir Mitchell in Philadelphia in 1878 (at the age of seven years), because of a lateral spinal curvature and some peculiarity in her walk. In the past five years the walk has become increasingly awkward and feeble. Staggers somewhat, and seems to make a special effort to plant her feet firmly. Walks a little more easily after getting started. The hands have been affected from an early period. Never had numbness or sharp pains. Menstruation not established. No eye symptoms. Health fair, but she is easily exhausted by efforts and tired by examination. Is more irritable than her sister, and her education has been neglected. The disease has advanced more rapidly in this than in the other cases.

Examination. — Eyes normal (ophthalmoscope not used); voice and articulation normal; no facial chorea. Hands are held out in extension very much like her sister's, with carpi over-extended and fingers separated. No tremor, but marked ataxia with rather more oscillation than in sister. Ataxia increased by closing eyes. Grasp very good for age; R., 14°; L., 12°, on a stiff dynamometer. Is able to dress herself, etc., and does embroidery.

Feet are like those in Case I., cold and bluish. In sitting posture they show a hollow sole and slight pes equinovarus. The tension of tendo Achillis cannot be fully overcome. In standing with bare feet the feet are in valgus. Right shoe-heel is worn away on its inner side, the left on its outer side. The walk is rather more uncertain than ataxic; does not stamp with heels. Closing eyes causes increase in staggering and ataxia. Pin-test on shoes shows no marked ataxia, but a little tremor of the foot. Goes upstairs quickly without support, but in a rather stamping way. In act of drinking, the ataxia is well shown, and also some difficulty in mouth swallowing (no dysphagia, strictly speaking). No tremors when quiet. Has an extreme lateral spinal curvature to the right in the cervico-dorsal region. Right scapula and hip project and seem larger. Heart free from murmur. Is infantile but intelligent, like a child of about ten years.

Second Family. — H——, of New York, three cases.

Family history.—Father a healthy man. Mother died of consumption at an unknown age. Nine children born. Several died when about four years of age (diseases unknown). One sister died of consumption; another sister had the ataxic disease from about her fifteenth year, and died when about thirty-five, after confinement; child also dead. She was always able to walk, though awkwardly and feebly. Two brothers were affected like her, and these I had an opportunity of examining in 1879.

Case IV.—J. H——, aged eighteen, came to my clinic at the College of Physicians and Surgeons, New York, on March 29, 1879. When he was seven years old his legs began to grow weak, and he staggered in walking. When about fourteen, was unable to run. Since that time the hands have been weak. The disability of the arms and legs has steadily increased. In the last three or four years he has had sharp pains, like needle-thrusts, in spots on the legs only. These pains occurred repeatedly in some spots, constituting a sort of paroxysm (fulgurating pains?). Never had numbness, diplopia, or dysphagia. Sight is dim, especially in the left eye. At times urine escapes involuntarily.

Examination.—Facial muscles, pupils, and ocular muscles normal. Ophthalmoscope shows partial atrophy of both optic nerves. The tongue is slightly ataxic in its movements, and presents fibrillary contractions. State of speech not noted (must have been normal). Grasp is good; R., 37°; L., 41°, on dynamometer (is left-handed). Hands typically ataxic. Walk is ataxic with large irregular movements. Over-extension in stepping. Sways at the hips. Needs support to stand with eyes open, and cannot stand with eyes closed. Resistance strength at knees good. In walking, tends to run forward. Has had several falls lately. Sensibility, tested only by pricking, is normal. No tremors when quiet. Unfortunately no mention is made of the state of the patellar or plantar reflexes.

Case V.—M. H——, aged thirty-two. I visited him at his home with Dr. W. R. Birdsall, on April 15, 1879. This man states that he first noticed difficulty in walking when fifteen years of age. At sixteen or seventeen was rejected by an army examining board as being "too light." At eighteen was obliged to use crutches, which he did for three years. Since that time (1868) has been obliged to go about in a little wagon, pushed or hauled by a friend. In this way he has begged on the streets for several years.

Arms and speech first affected about four years ago (1875) at the age of twenty-eight. Sometimes has had a strange feeling in the head for a few moments, but claims never to have lost consciousness. Memory is impaired; sight dim. For some time has noticed a loss of feeling in the lower extremities; cannot always tell where and how they lie without looking. Cannot feel light touch of a pin, but perceives severe pricking, and notices cold draft of air on his bare feet. Has had pains in his lower extremities which he calls "growing pains;" apparently not fulgurating pains. Constipation extreme.

Examination.—Face and tongue show fibrillary tremors. Speech thick and slow, a peculiar effort being required to bring out each word. Upper extremities very ataxic. In attempting to place forefinger on nose, goes wide of the mark; can carry a glass of water to his lips, but with difficulty. Strength is good; R., 42°; L., 42°, on dynamometer. Cannot stand. When seated cannot elevate or extend legs fully (this may be due to his sitting so many hours a day for years cramped in a small wagon). Is able to flex legs, but does this with exaggerated and irregular muscular actions.

Sensibility: On finger-pulps distinguishes points of æsthesiometer at from 5 to 10 mm. Feels pricking on hands and feet. Slight anæsthesia. He must be fed, dressed, and undressed by his relatives.

On account of peculiar speech, a silly expression of

countenance, and his ataxic movements has been arrested for supposed drunkenness several times.

All symptoms are progressive.

The briefest summary of these cases is that they resemble much more posterior spinal sclerosis than disseminated cerebro-spinal sclerosis. Yet they present features of difference from typical tabes, viz., the absence of pupillary symptoms, of fulgurating pains, of marked anæsthesia, and of stamping ataxic gait. There is in all the cases an element of paresis not observed in common posterior sclerosis, and which may possibly be due to varying degrees of antero-lateral sclerosis (as found in the cases hitherto examined post mortem, *vide* Dr. Ormerod's digest).

ON THE THERAPEUTICS OF DIGITALIS.

By THOMAS J. MAYS, M.D.,

PHILADELPHIA, PA.

No drug has received more scientific attention from pharmacologists and therapeutists than digitalis, and yet to any one who is conversant with the medical mind of to-day it is very evident that some confusion and vagueness exists concerning its mode of action, and its proper adaptation to diseased conditions. For example, the impression is afloat that digitalis slackens the heart's movements by stimulating a so-called inhibitory apparatus of the vagi, and that it exerts its therapeutic influence through this mechanism by actively lengthening the diastolic period, thus giving repose to the heart and allowing time to recuperate its waning energy. Then there prevails a belief, which probably springs from the inhibitory theory of its action, that digitalis does not give that real and genuine support to the heart which many are led to expect from it. Again, one of the most striking features in the range of the action of digitalis is its power to reduce the number of cardiac pulsations; hence it is often administered for the purpose of calming an excited heart when aconite, veratrin, and other agents are indicated. The hope that these misconceptions may be corrected is my apology for offering the following remarks on a subject as trite as that of digitalis.

Regarding the phenomena which are presented by digitalis in its action on man and animals there is no division of opinion. The first stage of its action on the circulation (and this phase of its action mainly concerns us here) consists in invigorating and retarding the pulsations of the heart and in elevating the blood-pressure; and the second stage is characterized by irregular cardiac action, systolic arrest, and diminution of the blood-pressure. The first series of phenomena is produced by small, and the latter by large doses. So far all are agreed, but when it comes to the interpretation of these phenomena, then it is that a wide divergence of opinion results.

One set of opinions holds that there exists in the pneumogastrics a bundle of nerves, the function of which is to interfere with, or counteract the function of other nerves in the heart, and that digitalis by acting on this inhibitory mechanism in small doses, interferes with the motion of the heart and thus it comes to beat more slowly. When large doses are given they are said to paralyze this inhibitory mechanism, and the irregularity in the heart's action and fall of blood-pressure is the result.

Another set of opinions holds that the first phase of digitalis action is due to a stimulating influence on the pneumogastric and cardiac nerves, and the second is due to a paralyzing influence on these same nerves. It may be said by the adherents of the first theory, in confirmation of their view, that electric excitation of the vagus arrests the heart. This is very true, but any one who has had any practical experience with arresting the heart in this way knows that the electric impulse which is required to arrest the heart is far too strong to be called stimulant, but rather paralyzes the higher cardiac nerve-centres, for the heart in a very short time after it is thus cut loose, and after it has recovered from the temporary shock, goes on beating as before, in spite of the operation of the electric current. Then, again, in electric excitation of the pneumogastric the heart is arrested in diastole, while digitalis arrests it in systole—a difference of significant import. Were those who hold the inhibitory theory consistent they would be compelled to restrict the action of digitalis to the diastolic period, while, as we have seen, the very opposite is true; but without entering into details it may be said that the warrant for the existence of such an inhibitory apparatus is resting upon an exceedingly feeble basis in the literature of experimental physiology, and that no proof has yet been offered in substantiation of it which has successfully outridden the test of time and of criticism.

Now from what has been said it is evident that a marked contrast exists between the action of small and large doses of digitalis. This is in consonance with what may be expected from a knowledge of the general operation of forces on the animal body. Small doses of any agent will invariably enhance the function of the organ on which they act, while large doses just as invariably depress it. This I have shown to be true of the action of nearly half a hundred elementary drugs,[1] such as the alcohol group, alkaloids, active principles, acids, and alkalies, on the isolated frog's heart. In no single instance did small doses of any agent fail to stimulate the action of the heart over and above that which it was normally capable of performing, nor did any of the agents fail to depress, or even to annihilate, its action in maximum doses.

Below will be found tracings obtained from digitalin in minimum and maximum doses, which may be taken as a specimen of those obtained from the other agents. (Tracings of intermediate doses of this and of other agents have also been obtained, but for brevity's sake will not be introduced here.) The first part (*a*) of the tracings is that which is given by the heart with a two

per cent. solution of blood, and is taken as a standard of what the heart can do when fed with its own pabulum and uninfluenced by any drug agency. The second part (*b*) represents the action of the heart under the influence of minimum doses (1:40,000) of digitalin, *i.e.*, one part of digitalin to forty thousand parts of the two per cent. blood solution. The third part (*c*) represents the behavior of the heart under the influence of maximum doses (1:1,000), *i.e.*, one part of digitalin to one thousand parts of two per cent. blood solution.

The value of these representations is found in comparing the higher and lower tracings obtained from digitalin with those obtained from the two per cent. blood solution alone. Thus it will be seen that if digitalin in the proportion of 1:40,000, or any other proportion, added to the blood solution produces higher traces than the heart can produce under the influence of blood solution alone, it is positive evidence that the digitalin added to the blood gives vigor and energy to the heart, which it cannot obtain from the blood solution alone. The converse of this is also true of maximum and intermediate doses. These tracings also show the characteristic systolic arrest of the heart by digitalis. The proportion of 1:1,000 gives strong evidence that it is the contractile and not the diastolic period of the heart's cycle which is affected, for the tracing is lifted far above the base line, and the diastolic period, as is shown by the slight undulations, is almost wholly obliterated and absorbed by the systole. The cause of this systolic arrest seems to be due to the fact that digitalis principally affects the nervous mechanism of the heart. For throughout my investigations I found that those agents which chiefly oper-

[1] See Therapeutic Gazette for February, 1885.

ate on the nervous structure of the heart, or rather, on its nervous irritability, produce systolic arrest, and those agents which mainly affect its muscular irritability cause diastolic arrest.

The tendency, then, of digitalis in small doses undoubtedly is to cause the heart to increase its work, and were it not for the fact that a counteracting force is called into existence by the same dose, the number of pulsations would in all probability be increased instead of being lessened. But digitalis contracts the blood-vessels, and in this manner raises the blood-pressure and increases a resistance to the heart's action. In nearly all conditions of health and disease this law that the pulse rate is governed by the amount of blood-pressure holds true, *i.e.*, when the latter is high the number of heart-beats diminish, and when it is low they increase. This drug, then, by inciting the heart to more powerful contractions, and by narrowing the blood-vessels, also drives the blood with greater velocity through its channels, and thus not only invigorates the circulatory organ, but the whole animal economy.

From what has been said I think digitalis has the same action on the heart, when this organ is isolated from the higher nerves and nerve-centres, as it has when in contact with these, and Ackerman, Donaldson, Stevens, and others have shown that it acts similarly on the blood-vessels when these are divested from the influence of the higher nerve-centres, and that it is not necessary, therefore, to call in the aid of a special inhibitory apparatus to make clear its mode of action.

The next point which will engage our attention is the belief that, when digitalis has reduced the pulse to forty or fifty beats per minute, muscular exertion, like exchanging the recumbent for the erect position, frequently causes the pulse to rise far above the normal limit, the heart receives no real and genuine support from its action. But when, as Professor Wood rightly says, the heart's pulsations are diminished to such a slow rate, the organ is verging on the point of paralysis, and is only able to perform the work required by the body in the lying position; but as soon as the extra demands necessary to maintain the body in the erect position are made upon the heart, it is unequal to the task and falters in the undertaking.

But it is not necessary to expose the patient so closely to the border line of paralysis in order to get the beneficial effects of digitalis; and I think the following observations, made on a case of marked aortic and mitral incompetency, associated with hypertrophy after the heart was reduced from ninety to seventy-two beats per minute by digitalis, and which gave the following pulse-tracing, shows very manifestly that the heart does obtain real power from this agent in proper doses: Lying down in bed, 72; sitting up in bed, 73; lying down in bed again, 72; standing up after lying down, 77; lying down after standing up, 72; standing up after lying down, 78; walking one hundred and twenty-eight feet on the level after lying down, 79; after walking up and down stairs from second story, 82; lying down after going up stairs, 72. The average pulse-rate in the male in health is, lying, 66; sitting, 71; and standing, 81, so it will be seen that in this case the oscillations in the pulse-rate were smaller in different bodily postures than in the normal.

From what has been said it is also evident that digitalis is indicated where there is a loss of tension in the heart and arteries, usually associated with a quick pulse. The loss of arterial tension not being taken into proper consideration, it is often erroneously administered in fever and in acute inflammations for the purpose of reducing the pulse, when aconite or veratrin should be given. While both of the latter agents, like digitalis, have the power to reduce the number of cardiac pulsations, they do it in a manner altogether different to that of digitalis. They chiefly act on the motor or muscular mechanism of the heart, and bring on diastolic arrest, while digitalis, as we have seen, affects the nervous apparatus of the heart principally, and produces systolic arrest. Then aconite and veratrin, and other agents of this class, only reduce the pulse the most effectually when administered in maximum, or paralyzing doses, *i.e.*, doses in which they manifest their toxic properties, and can therefore never be continued as long as digitalis, which slows the heart in minimum or stimulant doses. Then again digitalis is slow in its action, on account of its difficult solution in the body, while both aconite and veratrin are well adapted to produce that quick impression on the circulatory organs so desirable in acute inflammatory diseases by being easily dissolved and rapidly absorbed. With these distinctive differences in their action it is plain that the indication for digitalis is a contra-indication for aconite and veratrin, and clearly demonstrates the folly of administering digitalis, as is often done, in the first and second stages of croupous pneumonia, when the intense congestion, the threatened or existing exudation, the generally slow pulse, and the whole pathological aspect of the case denotes an already overburdened and over-distended arterial circulation—precisely the condition which the drug is calculated to assist in aggravating.

That quantity of digitalis which constitutes a stimulant dose depends upon the degree which the circulatory organs have departed from the normal line. In the weak heart and flaccid circulation depending on a valvular lesion, four to six drops of the tincture every three hours for the first day, and afterward every four hours, will generally suffice to bring relief. In this dose it also acts very desirably in acute diseases after the crisis has been reached or passed. It will add vigor to the fatigued and overworked heart, and assist it in passing this dangerous period. The same dose is also applicable in that form of bronchitis depending on cardiac incompetency, but acts best here in combination with small doses (ij. grs.) of iodide of potash, and sulphate of atropia (gr. $\frac{1}{300}$). In nervous shock, where besides an intense depression of the circulatory functions the nervous centres are blunted, larger doses (x. to xv. drops) are required, but its action is materially enhanced here in combination with sulphate of atropia (gr. $\frac{1}{150}$). Its action is, however, obtained the quickest when $\frac{1}{60}$ or $\frac{1}{50}$ of a grain of digitalin is dissolved in water and glycerine, one of the latter to ten of the former, and given subcutaneously. In delirium tremens and chronic alcoholism enormous doses of the tincture (fl. ʒ j. to fl. ʒ ij.) are employed to advantage. In fact, small doses are powerless to make any impression on the indurated nervous system. A safe guide in the administration of digitalis is to watch the urinary excretion, and to diminish the dose, or withhold it, as soon as the urine begins to be reduced in quantity.

151 North Fifteenth Street.

Pregnancy in a Young Girl.—Dr. F. C. Kinney, of Greensboro, Vt., sends the following report of a case of pregnancy occurring in a young girl. "At 2.30 A.M. April 18, 1885, I was called to see Miss E. W——, aged not yet thirteen years, as her father and older sister (her mother being dead) claim. Found her in labor; learned she had "been sick" since the 15th. Head presented and os dilated as large as a silver twenty-five cent piece. Warm drinks were administered, and at 6 A.M. I ruptured the membrane, but labor progressed very slowly, and at 10.30 A.M., the patient becoming rapidly exhausted, I applied forceps and delivered her of a fairly well-nourished, well-developed female child, weighing seven and a half pounds. The patient recovered without accident, and at this writing both child and child-mother are alive and doing well. The patient is rather large for her age, well developed and fleshy, and would weigh, I think, not far from one hundred and ten pounds. The only point in the case is the extreme youth of the mother, she being but twelve years ten months and sixteen days old at the time of her confinement."

EMPYEMA:

Its Treatment by Daily Aspiration through a Drainage-tube.[1]

By DANIEL MILLIKIN, M.D.,

HAMILTON, O.

For one neither skilled, nor experienced, nor greatly interested in surgical matters, to take up a subject which is essentially surgical in its nature, is a performance so strange that I protect myself in advance by a statement that I only approach the topic of empyema as a theorist. I merely throw out a hint of a new line of treatment, and seek rather to be instructed than to instruct.

Two or three years ago I had charge of a fine stalwart Irish-American patient, a male, twenty-two years of age. He had come home from a distant city, feeling that he was stricken with grave disease, and, like most men under such circumstances, wanting to see his mother. He developed a fine and typical case of typhoid fever, which reached and passed its crisis with violence, but left him in fairly good order.

When his evening fever was reduced almost to no fever at all, he developed a pneumonia in the left lung. This affection was also typical in its course. It extended from the apex so far as to involve about one-half of the lung. Resolution began in due time and proceeded rapidly. When he began to go about and to be ravenously hungry, I saw him only occasionally, and, I think I had determined to see him no more when I was called back by his faithful mother.

I found universal dulness over the left side of the chest. The man was positively panting. His face was livid. His pneumonia, while resolving, had become a pleuro-pneumonia, and the left pleural cavity was full of pus.

His distress being very great, I made all haste to aspirate, and obtained a great quantity of very offensive pus. Two or three days afterward I aspirated again, and drew off a small quantity of pus, to be sure I was in the pleural cavity. Then, using the aspirator-needle as a guide, I passed a very small knife alongside it into the pleural sac. Into the wound so enlarged I slipped a grooved director. The needle was then withdrawn, and a small Nélaton catheter was passed on the director. Through this catheter, which was thereafter to perform the functions of a drainage-tube, I aspirated a small quantity of pus, to be again assured that I was in the pleural sac, and then I withdrew the director.

The treatment consisted in a daily withdrawal of pus, until the patient complained of tightness, oppression, or pain. He then entered his protest against further aspiration, and a quantity of some antiseptic fluid was thrown into the chest through the catheter. Fluid was withdrawn and injected at each sitting until it returned limpid and clear, and, at the end of each sitting, it was so thoroughly withdrawn as to leave the patient in some slight distress. The whole work was done with the aspirator, which constantly informed me of the quantities of fluid withdrawn or injected, and also informed me approximately of the amount of tension or of vacuum produced at any time. Recovery was rapid and complete, notwithstanding that the patient had been reduced by long illness before the development of the empyema.

While this case was still in my hands, I sent a tuberculous youth of nineteen years to New Mexico, and on the way thither he developed a pleurisy which proved to be purulent. He lived in New Mexico for some weeks with his chest full of pus, and finally dragged himself home to die. The condition of affairs being determined soon after his arrival, I proceeded as in the case just narrated. Little hopes were entertained of a cure, because, for a long time, various physicians had endeavored to "dry up" a suppurating ear and a small sinus at the margin of the anus, and it had always proved to be true, as his friends had said, that nothing would heal on his person. When attacked by the purulent pleurisy he had already travelled far toward that extreme emaciation which we agree with the laity to call consumption.

He died, about as would have been expected by any one who had studied his case, with every sign of tuberculous excavation of the uncompressed lung, but long before his death the pleural cavity which I had been treating by daily aspiration through a drainage-tube had healed completely. The perineal sinus and the ear continued to suppurate a little, but the pleurisy healed itself in the very presence of a consumptive decline.

I trouble you with these two cases only (for that ends my experience of cases so treated), and I venture to lay down the following principles of treatment, not dogmatically, but soliciting your discussion and correction:

1. There is an advantage in the small opening in the wall of the chest. Other things being equal, a small hole in a man's skin is better than a large one. Other things being equal, one hole is better than two. Except upon some urgent indication, clearly shown, we have no right to attack a rib.

2. It was a positive blessing to these patients that the pus only flowed while the doctor was present, and that the clothing was clean in the intervals of his visits.

3. This leads me to say that the joint between the tube and the wall of the chest was not only tight at the beginning, but it remained so, rarely permitting the escape of a drop of fluid and never permitting the entrance of air. After each sitting the end of the tube was closed by applying to it a pair of flat pincette forceps, which were then laid flat on the side of the chest to be secured there by adhesive strips. Since the forceps were always laid on the same spot, or nearly the same, the process of absorption gave to the catheter an oblique entrance into the chest such as the ureter makes into the bladder. The entrance was therefore always valvular, and, while fluid occasionally found its way out of the chest, I could never perceive that air passed in, no matter how thorough was my aspiration. The few granulations that sprang up about the wound appeared to make the orifice more strictly valvular.

4. The tube was always safe; there was no possibility of its slipping into the chest through any carelessness of the patient or any soaking of the dressings. A recent article in the New York Medical Record will convince any one to the contrary who assumes that there is no danger of the ordinary drainage-tube slipping into the chest. The production of a slight vacuum with each inspiratory movement does certainly invite this very accident, and in the article to which I allude, scores of cases are reported which represent an untold and unspeakable amount of risk and suffering. As I treated the cases of which I speak, the pincette forceps were never removed from the end of the little catheter which served me for a drainage-tube until the catheter had been already connected with the aspirator, and, as a matter of routine, the tube was never disengaged from the aspirator until the forceps had been again applied. There never was a time when the tube was not attached to the aspirator, except when it was pinched by the forceps, and it was manifestly impossible for them to be dragged into the chest.

5. It is hardly worth while for me to lay down the very evident principle that, before a purulent pleurisy can be healed, expansion of the lung on the affected side must take place, or collapse of the affected side of the chest must occur to close the abhorrent vacuum. It may, however, be worth while to remark that any sort of treatment which directly solicits the expansion of the lung, and, failing that, the collapse of the chest, is commendable. Using the aspirator as I did, it was my policy to make such suction as would cause some slight but unequivocal distress at each sitting, and, on the other hand, when I replaced the pus by throwing in some antiseptic fluid, I took pains to throw in less—always less—

[1] Read before the Ohio State Medical Society, June 5, 1885.

fluid than I had withdrawn. It will occur to you that the aspirator made me master of all degrees of tension or of vacuum, and furnished me with a constant and accurate measure of the fluid injected or withdrawn.

I would not be tedious, but I desire to insist that the lung on the affected side was subjected to a daily stretching by the aspirator, such as it could have had by no other convenient means, and such as it could not have had at all with a free opening in the chest. If I may judge by the feelings of tightness and oppression which my patients complained of, I am assured that I commonly left them with a partial vacuum, which persisted to an appreciable degree for nearly an hour, and I venture to say that this was a very valuable sort of movement-cure to the lung itself. In short, the treatment pursued expanded the lung, and I do not know of any other treatment which does this, nor, indeed, of any which does not directly favor the collapse of the lung.

6. In cases where, for any reason, the lung cannot expand, the cure can only be accomplished by a partial collapse of the chest-wall, and this, also, is favored by the partial vacuum which I recommend to be established within the chest.

The same claims may be made regarding the mediastinal boundary between the pleural cavities. The daily aspiration which I recommend solicits the mediastinal structures to present a convexity to the affected side of the chest, and thus to give to the sound and expansible lung the more room to perform its vicarious functions.

7. The aspirator used for drainage and cleansing of such a diseased pleural cavity has the further advantage of causing drainage without regard to gravity. When suction is made, the tendency of the pus is constantly toward the point of least resistance, which, in this case, will be at the point of the catheter. Supposing the lung to be expanded and more or less accurately applied to the chest-wall, it must squeeze out the pus from all parts of the pleural cavity to that point where suction is already inviting it. Up-hill or down, the tendency is for pus to travel to the point of the catheter, and, theoretically at least, this seems to be much more scientific and precise than to depend on gravity to lead the fluid to an opening, or to two openings, when we know well that gravity cannot coax pus out of a depending pocket, if any there be.

Double Ovariotomy in Acute Peritonitis.—Dr. Justus Ohage, of St. Paul, Minn., reports a case of this kind in which he operated successfully, and in a manner most creditable to himself. He says, with regard to laparotomy in septic peritonitis: "Nussbaum, of Munich, a few years ago, was the first to propose laparotomy and disinfection of the peritoneal cavity as a cure for the otherwise always fatal septic form of peritonitis. A few courageous surgeons followed his teaching, and Czerny, Nussbaum himself, and Schede, I think, did so successfully. One of the boldest and most successful steps in this direction was taken by Bull, of New York, who, on thorough and scientific reasoning, opened the abdomen, sutured the bowels—perforated by a bullet at five different places—disinfected the peritoneal cavity, and saved his patient from an inevitable death. Kocher, of Berne, successfully treated a shot-wound of the stomach by a similar operation, while Kinloch and Lloyd were unsuccessful. Now, if these few cases do not prove that septic peritonitis can be cured by laparotomy and disinfection, they at least prove that some otherwise hopeless cases are saved thereby, and this alone is sufficient cause to resort to it under similar circumstances; but resort to it early, and do not wait, as is often done in tracheotomy, *i.e.*, until it is too late."

The Head of the Leech contains a secretion which prevents the coagulation of blood. In experiments, Professor J. B. Haycraft, who noted this fact, uses an extract of leech, a few drops of which are sufficient to prevent coagulation.

CONTAGIOUS OPHTHALMIA IN ASYLUMS AND RESIDENTIAL SCHOOLS.

By RICHARD H. DERBY, M.D.,

SURGEON NEW YORK EYE AND EAR INFIRMARY.

Before asking the attention of the Academy to a paper of some length on the subject of "Contagious Ophthalmia in our Asylums and Residential Schools," the writer desires to state that the interest attaching to this subject is not of a purely scientific nature, but appeals to the hearer on the threefold ground of philanthropy, medicine, and social science. The writer also holds that no one familiar with the subject will deny that contagious ophthalmia is a disease as dangerous to sight as scarlet fever and typhus and other contagious diseases are to life and health, and that the welfare of those who have been adopted by our public institutions, and for whom we are in great measure responsible, demands some system of quarantine or medical supervision which shall not only insure recovery to those already afflicted, but which shall afford ample protection to those who have thus far escaped contagion.

There is probably no gentleman here present who has given particular attention to diseases of the eye, who will not bear witness to the fact that any child who is an inmate of our public institutions, is far more likely to lose his sight from the inroads of contagious ophthalmia than to lose his life from scarlet fever or any of the diseases which are subject to quarantine regulations by the Board of Health.

The writer would further state that, whereas the dangers from neglect are comparatively great, the disease itself is perfectly amenable to treatment, and the reward which is to be expected from an *adequate* appreciation of, and attention to, the exigencies of the case is such as to render further neglect of the subject entirely inexcusable. This is his apology, if apology is necessary, for asking his hearers to follow him in the exhibition of statistics which, on a more trivial subject, would be considered dry and uninteresting.

In October, 1884, the writer of this paper prepared, for the Committee on Hygiene of the County Medical Society, a report on "Contagious Ophthalmia" in three of the asylums of this city. Since that time many other institutions have been visited and the inmates examined, and we are now able to present a summary of results obtained from the examination of seven thousand four hundred and forty children, the entire number contained in twenty-four orphan asylums and residential schools of this city. Before detailing the results of these investigations, a brief description of the disease we are considering may be permitted. Blenorrhoic conjunctivitis in its chronic form is characterized by injection of the conjunctiva of the eyelids, hypertrophy of the papillary bodies, and secretion of a purulent or a muco-purulent nature. The conjunctiva tarsi of the fold of transmission, the semilunar fold, are in general the seat of the disease, while the conjunctiva of the eyeball may, and generally does, in the earlier stages of the disease, escape.[1]

The secretion is contagious. At an early period of the affection the meibomean glands are no longer to be seen upon eversion of the lids; later on, the swelling of the semilunar fold increases, as does that of the fold of transmission; the inner canthus ceases to be sharply defined; the tear-points are disturbed in their position, and the passage of the tears interfered with. If the disease progresses, the conjunctiva of sclera participates in the affection; it becomes injected and shows serous infiltration, and at a later period these symptoms are intensified; the ocular conjunctiva becomes swollen; the lids can with difficulty be everted; there is chemosis; the cornea is now in danger. Pressure of the swollen lids and of the chemosis upon its nutritive supply, lead to ulceration upon its surface, and unless relief in some

[1] Graefe und Saemisch, Band IV., pp. 76 to 79.

way is found, perforation of the cornea and consequent prolapse of the iris may ensue.

Blenorrhoic conjunctivitis in a vast number of cases remains an affection of the conjunctiva of the lids, and does not advance to the later stage which we just briefly described.

It passes for a catarrhal affection of the eyes, and as such is treated; or it exists, and this is often the case, without receiving any medical attention whatever. We have spoken of the secretion from a blenorrhoic conjunctiva as contagious; it may be transferred from eye to eye by means of a towel; it may be conveyed in the water used for washing; the atmosphere itself may be the bearer of the contagion.

Among soldiers in their barracks, in the crowded holds of vessels, in the over-filled homes of the poor, among the inmates of large institutions, contagious ophthalmia has been found, and as our investigations will show, an especially fertile field for this disease, so full of danger to the eyes, exists in the orphan asylums of a great city.

In an experience of fourteen years as officer of one of the largest ophthalmic hospitals of the county, the writer has over and over again had children brought to him from some of our city institutions with their sight irreparably damaged, and with the sad statement, doubtless true, that before they were taken from their homes their eyes were perfectly sound. It was with a view of seeing how far this malady might exist among the children cared for in the asylums of this city that the investigations now detailed were made.

The first asylum visited stands on one of the broad avenues of the city, on high ground. The children were examined in their class-rooms, and subsequently their dormitories and lavatories were visited. Among the boys, of whom there were 326 present, were found 96 cases of contagious ophthalmia; among the girls were 65 cases out of an attendance of 331, making a total percentage of 24.5. In almost all the cases here found the disease was in what we have described as the first stadium. In many cases the appearance of the eyes before eversion of the lids betrayed no sign of the malady which was present. In certain cases, the child or its attendant remarked that it had from time to time a cold in its eyes, nothing more. Occasionally, where the blenorrhoic process was most strongly marked, neither child nor attendant seemed aware that anything was wrong. In the dormitories each child had its own bed; in the wash-room, separate towels hung upon numbered hooks, and no basin was used; small jets of water at intervals of a foot along a horizontal pipe placed above the sink, furnished each child with its supply for washing. In the boys' asylum a large sunken tub, perhaps ten feet long, was prepared for the bath, and in this eight children or more at a time were bathed. (Eight years ago I visited this same institution with the late Mr. Theodore Roosevelt. The object of the visit was to ascertain to what extent contagious ophthalmia then existed among the inmates. The notes of that examination were not preserved, but a large number of children were found then to have sore eyes. In the lavatories were a few roller-towels hanging on the wall, and these were used by the children indiscriminately, those that had eye trouble and those that were well. It was in consequence of representations we then made that the children were thereafter supplied each with its own towel.)

The next asylum, which we may designate as No. 2, showed among 1,586 inmates, 488 cases, or 30.7 per cent. of contagious ophthalmia.

In No. 3 were 782 inmates; of these 111 had sore eyes, or 14.2 per cent. In the lavatories hung on the walls twenty-five roller-towels, and these the attendant said were changed two or three times per week.

In No. 4 were 188 children, and of these 93 or 49.4 per cent. had sore eyes. In reference to the condition of things at this asylum, I make the following extract from a letter received May 27, 1885, from the physician in attendance: "When you made an official visit to our institution, in 1884, you found 92 children suffering from a contagious type of ophthalmia. . . . At your suggestion the sore-eyed children were separated from the others, and subjected to a daily course of treatment for a period of five months, the present time of writing. I give the result—42 of the 92 are cured. Fifty of the whole number in the institution are still under treatment. . . . Two children never occupy the same bed; a towel and brush is supplied to each individual. The bathing facilities are of the best, the grounds are ample, and the children have an abundance of out-door life. The dietary is excellent, and in a family of 200 it is but seldom that a child is so ill as to require the aid of a physician."

In asylum No. 5 were 740 inmates, and among them 71 cases, or 9.5 per cent. Here we found two large rooms, with two immense bath-tubs in each, about which 260 boys stand twice or three times a day and wash at a spigot, and then go irregularly to one of the sixty roller-towels that hang on the walls of each room.

In asylum No. 6, out of 96 inmates were 26 cases, or nearly thirty-seven per cent.

In No. 7 were 15 cases among 262, or 5.7 per cent.

In No. 8 were 455 children, and of these 74 had sore eyes, or 16.2 per cent.

In No. 9, out of 155 children, 5 were affected, or 3.2 per cent.; each child was supplied with its towel.

In No. 10 were 240 children; there were 15 cases of sore eyes, or 6 per cent. These children were for the most part committed by the courts; each child had its own box containing towel and brush.

In No. 11 were 21 children, and no case of granular ophthalmia.

In asylum No. 12 were several buildings. In the first one visited I found 80 boys, from four to eight years of age. There were 47 cases of contagious eye-trouble. The cases were mostly severe, with free secretion. Of 164 girls there were 80 cases of similar type. Louisa M——, aged four years, came to me the day before, at the New York Eye and Ear Infirmary, with left eye in condition of central corneal perforation and extensive prolapse and acute granular ophthalmia. The mother said the child had gone into the asylum with good eyes, and had been there one year. The sisters in charge of the asylum remembered the case, and said they had sent the child out to have her eye operated (*sic*). The eye was beyond hope. Of 178 boys there were 56 cases; of 29 infants under three years of age there were 21 cases. With these last the practice of the attendants was to use two towels, one for the sick, the other for the well eyes. In the case of the older children, each had its numbered towel. To summarize: among 451 children were 204 cases of contagious ophthalmia, or 45 per cent. There was every evidence of over-crowding in this asylum; no plan had been, or apparently could be, adopted for isolating such children as suffered from this grave disease. The sisters in charge stated that they must receive all the children that were sent to them, whether they had sore eyes or not, as they were for the most part commitments. The general physique of the inmates was not good, and the evidence their evening meal gave of the dietary was not encouraging.

In marked contrast to this was asylum No. 13. The fine physical condition of all the children was noticeable. Each child had its own brush, comb, tooth-brush, and towel. The towels were changed twice every week. Of 104 inmates there were 6 cases, or 5.7 per cent.

In No. 14 were 310 boys, and of these there were 73 cases, or 23.5 per cent. The large building in which these boys were cared for furnished each child with a small wire-screened compartment, in which stood his bed and wash-stand. In the infirmary were 14 children, all with recognized sore eyes, but the 50 and more cases found among the larger boys had received no attention, so far as inquiry among the boys and their attendants showed, from the medical officer of the asylum.

In No. 15 the children were found distributed in cottages, each child with its own towel, brush, etc.; of 151 children there was 1 case, or less than one per cent.

In No. 16 the children were arranged as in No. 15. Here was 1 case among 122 children, or .08 per cent.

In No. 17, the asylum a large and spacious new building, the children were well cared for. Among 399 children were 7 cases, or 1.7 per cent.

No. 18 contained 245 children, and among them were 40 cases of contagious ophthalmia, or 16 per cent. In the nursery department were half a dozen towels used at the discretion of the attendants. In the wash-rooms for the older children hung numbered towels.

In No. 19 were 98 children and young women, and among them were 2 cases of contagious ophthalmia, or about two per cent. The dormitories were spacious, well ventilated, and each inmate had its own towel.

In No. 20 were 124 girls, and among them 6 cases, or 4.8 per cent. Each child had its own numbered towel.

In No. 21 were 132 girls, and among them 21 cases, or 15.9 per cent. The school-rooms and dormitories were dark and badly ventilated. Each child was provided with its own towel.

In No. 22 were 18 girls between the ages of six and thirteen. In No. 23 were 22 young women. In neither asylum were any cases. Both of these asylums were in private hands, and the inmates cared for in commodious houses.

In No. 24 were 82 children, and among them 8 cases, or 10 per cent.

The communicable eye-diseases observed in these investigations have been designated under the general term of contagious ophthalmia. Among them were those where the true granulations, the so-called trachoma of Arlt, were present; others that might be more properly described as chronic conjunctival blenorrhœa. In some the affection had extended to the cornea, producing pannus, and in certain cases corneal ulceration had been followed by prolapse of the iris and adhesion. In striking illustration of the communicability of the disease, it was often noticed that when a pronounced case was found, a group of children presented themselves in succession with the same trouble, and these were children who habitually in the class-room occupied adjacent seats.

It is not the purpose of this paper to consider in detail the various causes which lead to the development of contagious eye-diseases in the asylums which have been visited. The part played by imperfect quarantine, bad lavatories, overcrowding, bad hygiene—all this has been discussed in other places.[1]

My purpose in these investigations will have been attained if I have drawn attention to the fact that in the asylums of our city, where children in large numbers are housed, and where the inmates are taken from the overcrowded, illy ventilated, unhealthful homes of the poor, there exists to an alarming extent a disease fraught with danger to the eyes of all assembled there. We have seen that this affection may be present without attracting the attention of the lay attendants of the children, and without calling for or receiving the care of the visiting physician of the institution. In certain cases, it is true, if the subject is well nourished, and the hygienic surroundings good, the eye-trouble disappears without treatment. In too many cases, however, the disease, which has once established itself, goes on insidiously undermining the health of the eyes, and there comes a period when the affection is acute, and we hear of an epidemic of contagious ophthalmia. Fortunate, then, are the unhappy inmates of such an institution, if many eyes are not lost before the disease can be controlled. The statistics taken from these asylums are appalling enough. We have found among 7,440 children that 1,428, or 19.19 per cent., nearly one out of every five, had communicable eye-disease, which he was liable to transfer to his neighbor. Nor does the trouble cease here, as has been observed in several of the institutions we have visited. So soon as an unusual number of children are found to suffer from sore eyes, it is not an uncommon practice for those who have the children in charge to send back to their former homes the worst cases, with the statement that it is better that, until the child recovers, treatment should be procured outside of the institution; only those who are familiar with the homes of the poor in a great city can appreciate what a hardship is now wrought upon the unhappy guardians of such children. It is impossible that a child afflicted with contagious eye-disease should receive in its tenement-house home adequate treatment. This class of cases is often refused shelter in our best equipped eye infirmaries. The child must be brought three times, at least, in the week to the clinic for out-door patients. The already overtaxed parent must see to it that this frequent attendance is not neglected. The child becomes a fresh centre of contagium in the crowded, illy-cared-for home, where the food-supply is scanty and the simplest rules of hygiene are neglected. The case must often be neglected, and neglect means advance of the morbid process, permanent, irreparable damage to the eyes.

Were there time in this report, it would be proper to show how, by reason of a *per capita* allowance from city or State, it is in many of the institutions a pecuniary advantage to the asylum itself to receive as many children as possible within its walls, and overcrowding is thus directly encouraged. In many asylums children are committed by the civil authorities, and in others by charitable societies, whose object is the protection of their charges from cruelty at the hands of their natural guardians. Can a more refined cruelty be imagined than one which subjects a child with healthy eyes to the dangers which every epidemic of contagious ophthalmia carries with it?

This present report covers but a portion of the asylums of this great city. There are many others that we have not visited which would doubtless contribute their considerable quota of cases of communicable ophthalmia.

To meet this evil, certain conclusions force themselves upon us.

Under no circumstances should children be received in an asylum until a competent authority has pronounced the eyes of the new-comers free from any trouble of a contagious character. Every asylum and residential school of the city should be called on to furnish to the Board of Health a statement certified to by its attending physician, of the number of cases of contagious eye-disease at present within its walls. These cases should be separated from the other inmates of the asylum, and this quarantine should be rigidly enforced so long as a single case of this disease is observed. Adequate treatment must be supplied—not merely local treatment for the eyes, but such allowance of food and air as are necessary for the proper treatment of such cases.

No less precaution for the safety of other inmates of these institutions should be taken where contagious ophthalmia is found to exist than is now observed when a case of scarlet fever is recognized.

It is impossible to read the statistics which have been presented in this paper without acknowledging the fact that a great evil calls urgently for prompt and systematic action for its relief. What shall be done, and where shall the beginning be made? Our present inquiries have brought to our knowledge enough cases of contagious eye-disease to more than fill a large hospital devoted to this particular class of diseases. If such a hospital existed, it would undoubtedly soon reduce the percentage of such troubles to a minimum. Such a hospital would receive and care for all cases of communicable eye-disease until they could be returned cured to the institutions from which they were gathered. While we may not ourselves establish and maintain such a hospital, it behooves us as members of the Academy to make emphatic protest

[1] State Board of Health of New York, No. 44.

against the continuance of the present dangerous and inhuman practices which we have found at many of our city's institutions. Hoping that the members of the Academy here present will deem this matter worthy of their serious attention, I take pleasure in submitting it to their consideration.

ON THE RELATIVE VALUE OF MERCURIC CHLORIDE AND THE HYPOCHLORITES AS DISINFECTANTS.

By J. R. DUGGAN, M.D., Ph.D.,
FELLOW BY COURTESY IN THE JOHNS HOPKINS UNIVERSITY
AND C. T. McCLINTOCK, A.M.

The recent report of the Committee on Disinfectants of the American Public Health Association, in which they recommend mercuric chloride and sodium and calcium hypochlorites for all disinfecting purposes, makes a discussion of the relative merits of these agents a timely one. Assuming that these are the most available disinfectants—and this we think no one acquainted with the subject will question—what are their respective advantages and disadvantages when applied to the various purposes for which disinfectants are now used?

In the first place, as to cost, all are cheap, and none of the solutions of proper strength for use should cost over five cents per gallon. This is in marked contrast to the price of the majority of proprietary preparations of this class, the best of which when properly diluted cost far more than this. As regards odor, that of chloride of lime is objectionable, but that of its solution is less so, while the slight odor of the solution of sodium hypochlorite is not disagreeable. One of the principal advantages claimed for corrosive sublimate is that it is odorless; but we doubt if this renders it more desirable for general use, since, on account of its extremely poisonous nature and the absence of color, accidents are liable to happen from mistaking it for numerous similar salts or solutions in common use.

To destroy odors, which is one of the requirements of a good disinfectant, the hypochlorites are undoubtedly our best agents, since they act by oxidation and not by substitution. They also destroy the poisonous volatile products of putrefaction, and these bodies, there is reason to believe, are of more importance in the causation of disease than is usually supposed. The experiments of Le Bon (*Comptes Rendus de l'Acad.*, 95, 259) showed that the volatile alkaloids given off from material that had undergone putrefaction by non-pathogenic organisms, produced toxic symptoms when inhaled in very small quantities. For these reasons the hypochlorites are well adapted for use in privy-vaults or other places where refuse material is stored.

Notwithstanding the claims of some manufacturers, all the soluble salts of mercury injure lead waste-pipes by precipitation of the mercury, and the formation of a brittle amalgam with the lead. The insoluble salts are, of course, valueless as disinfectants.

For the disinfection of all material containing albuminoid matter, such as fæces, sputum, etc., the diffusive or penetrating power of an agent does much toward deciding its value; and it is here that probably the principal objection to corrosive sublimate is found. This salt forms with albumen an insoluble compound which retards its diffusion, especially when the material is semi-solid or solid. Not long ago Lister (*The Lancet*, October 25, 1884, page 723) claimed that a large excess of albumen caused the precipitate to be redissolved, but our experiments thus far have not confirmed this conclusion. It should be stated, however, that Lister used for his experiments the serum of horse blood, while we have used egg albumen; and it is possible that the albumen from different sources acts differently. We have found that the double chloride of mercury and sodium (or any alkali metal) has much less tendency to coagulate albumen than mercuric chloride alone; and if a solution of albumen contains much of this salt, no precipitation takes place when corrosive sublimate is added. The double salt that is formed under these circumstances is extremely soluble, and therefore readily diffusible. It is possible that Lister's results were due to the presence of sodium chloride in considerable quantity (about one-half per cent.)in blood serum, and we hope soon to be able to undertake some experiments on this point.

As the antiseptic and germicidal power of mercuric chloride is not diminished, but probably increased by the presence of sodium chloride, its addition to solutions of this agent for disinfecting purposes is very desirable. We are aware that ammonium chloride is used to increase the solubility of mercuric chloride, but we think we are the first to call attention to the action of these salts in preventing the coagulation of albumen. The amount of sodium chloride required to effect this is proportional to the amount of albumen present, rather than to that of the mercuric chloride; but even when there is too little to entirely prevent precipitation, a considerable part of the mercury is held in solution.

The hypochlorites are especially well suited for the disinfection of all albuminoid matter on account of their oxidizing and disintegrating action. They also have the advantage over solutions containing mercury, of not affecting lead waste-pipes. In cities where refuse matter is used for fertilizing purposes, it is possible that the extensive use of mercuric chloride might render such material injurious to vegetation, and to the soil to which it was applied. It seems to be well established that a soil free from microscopic organisms will not support plant life. This, of course, is of interest from a point of economy rather than that of sanitation.

In the important requirement of antiseptic and germicidal action, both mercuric chloride and the hypochlorites rank very high. As regards the first of these agents, different observers vary greatly in their figures. Since the percentage of any agent necessary to produce antisepsis varies greatly with the culture-medium used, results are comparative only when obtained under the same conditions as regards culture-medium, species of bacteria, method of inoculation, etc. Jalan de la Croix, who has probably done more than any one else toward increasing our knowledge of antiseptic action, states that 1 part of mercuric chloride is required to 25,250 of bouillon to prevent the development of bacteria introduced into the liquid by the addition of a few drops of broken-down bouillon. For fresh, uncooked meat-juice, he found that 1 to 7,168 was required to prevent putrefaction on exposure to the air (*Archiv fur exper. Pathologie*, xiii., 175). Koch states that the extreme dilution of mercuric chloride of 1 to 300,000 will prevent the development of the spores of *Bacillus anthracis*, and that the spores are destroyed by 1 to 10,000 ("Mittheil. aus d. k. Gesundheitsamte," Berlin, 1881). Our own experiments on the antiseptic action of this agent, made for the most part with a neutral one per cent. solution of Liebig's extract, inoculated with the bacteria of putrefaction, agree pretty closely with those of Jalan de la Croix. We have not yet satisfied ourselves as to its exact germicidal power, but find it to be somewhat less than is claimed by Koch. In fact, no other observer has succeeded in obtaining so favorable results as this distinguished experimenter. On the contrary, however, after most carefully repeating Klein's experiments, we cannot in any way confirm his remarkable statement that a one per cent. solution of corrosive sublimate has no action on spores of *B. anthracis*.

The hypochlorites owe their disinfectant value to the oxidizing action of the chlorine which they contain; but it should be remembered that chlorine combined in this way has twice the value as an oxidizing agent that it has when free. The hypochlorites furnish, in fact, simply a convenient method of storing and applying chlorine,

which, although a most valuable disinfectant, is, in the gaseous form, impracticable for general use. The sodium and calcium salts of hypochlorous acid have about the same germicidal value, while the potassium salt, on account of the fact that it contains proportionately less chlorine, is slightly inferior. It has been shown by one of us (Duggan: *Medical News*, Philadelphia, February 7, 1885) that chlorine, in combination as a hypochlorite, will destroy spores of *B. subtilis* and *B. anthracis* in two hours when the proportion is 1 to 1,666, and almost instantaneously, in less than one minute, when it is 1 to 400. Jalan de la Croix found the antiseptic power of the chlorine in chloride of lime to be equal to that of corrosive sublimate, the culture-medium being fresh bouillon inoculated with the bacteria of putrefaction. Our own experiments with sodium hypochlorite have given similar results.

Regarding the relative advantages of sodium and calcium hypochlorites, Price alone is in favor of the latter; but this is for most purposes more than compensated for by the fact that the solution of the former is almost entirely free from odor, and that it leaves on evaporation only sodium chloride, instead of the hygroscopic and disagreeable calcium chloride. Moreover, it does not render water hard and unsuited for washing purposes, as does the calcium salt.

The bleaching action of the hypochlorites is an objection to their use for some purposes; but it is for the most part cotton goods dyed with vegetable colors, which would be injured by water alone, that are affected by a hypochlorite in solution of proper strength.

For washing surgical instruments mercuric chloride is objectionable, on account of its action on silver and nickel. The hypochlorites will also tarnish silver slightly, but it may be easily cleaned with a little dilute ammonia water.

The question of the poisonous action of mercuric chloride, when used for injections, dressings, etc., is an important one, but does not come within the scope of our investigations.

In view of the facts mentioned, we think the solutions of sodium and calcium hypochlorites recommended by the committee of the Public Health Association are well adapted to disinfecting purposes, but where it is desirable to use mercuric chloride, we would suggest the addition of sodium chloride. A convenient strength would be 1 to 500 (about an ounce to four gallons) of mercuric chloride, and 1 to 50 (about ten ounces to four gallons) of sodium chloride. Since the addition of the permanganate recommended by the committee is sometimes objectionable, the solution can be conveniently colored by means of a little ordinary washing-blue. Either soluble Prussian blue or indigo will answer, and only enough to give a distinct color should be added. This will not color clothing placed in the solution, while the blue color is more distinctive than that of permanganate, which might be mistaken by children for fruit juice or wine. It might also be well to add a few grains of thymol to each gallon, as this will give a distinct odor that is not at all disagreeable. A concentrated solution of the double chloride of mercury and sodium may be made by dissolving, in ten parts of water, one of sodium chloride and two of mercuric chloride; each ounce of this is sufficient to make about a gallon and a half of a 1 to 1,000 solution. As sodium chloride can always be easily obtained, it would be well in using this solution to add more of this salt when it is diluted.

It would be more convenient if the two hypochlorite solutions recommended by the committee of the Public Health Association contained the same amount of available chlorine, so as to allow the same dilution. A pound of bleaching-powder to a gallon of water will give a solution containing about three per cent. available chlorine, which corresponds to the standard adopted for the sodium hypochlorite solution. These solutions may be diluted for general use with from ten to twenty parts of water. In dissolving bleaching-powder it should first be made into a paste with a little water, and then the requisite quantity of water added. This prevents the formation of masses which remain dry in the interior and dissolve with difficulty.

In conclusion, it should be stated that the attempts of manufacturers and others to combine mercuric chloride with a hypochlorite is impracticable, on account of the precipitation of the mercury as oxide. The value of any mixture whatever over the solutions mentioned is extremely doubtful, and often results in a chemical decomposition, especially when a hypochlorite is used.

Baltimore, May 14, 1885.

PULSATING PROPTOSIS AND ELASTIC TUMOR OF LEFT ORBIT,

Consequent upon a Trauma of the Skull—Ligation of Left Common Carotid.

By ROBERT SATTLER, M.D.,

Ophthalmic Surgeon to the Cincinnati Hospital, Cincinnati, O.

That rare lesion, of which abnormal prominence or proptosis and pulsation of the eyeball constitute the most conspicuous features, and which by earlier writers was described under a variety of names, is of interest to the surgeon principally because numerous distinct pathological lesions have been discovered on post-mortem examination.

The list of names includes aneurism by anastomosis,[1] aneurism of the ophthalmic artery,[2] erectile tumor of the orbit,[3] rupture of an aneurismal dilatation into the cavernous sinus,[4] vascular protrusion of the globe,[6] pulsating tumor of orbit,[6] rupture of the internal carotid and arterio-venous communication within the cavernous sinus,[7] pulsating exophthalmus,[8] etc. If, however, the selection of a name has been difficult, for the reason that a uniform pathological alteration, either intra- or extra-orbital, was not upheld by the results disclosed in the fatal cases in which a post-mortem examination was practicable, the orbital lesion, with its traumatic or idiopathic-spontaneous origin, nevertheless remains an interesting and rare one.

The uniformity and prominence of the clinical features of this lesion are particularly conspicuous, and they constitute a most typical group of phenomena. It is, therefore, not surprising that attempts should have been made from the earliest times to associate them with, and make them dependent upon, a definite pathological lesion. The earlier reported cases—1809 to 1850—were interpreted by the aid of the then current and most generally accepted theories. Pathological evidence was meagre and the results[9] from treatment (ligation of the common carotid) so uniformly successful that many speculative assertions were advanced, based only on clinical interpretation and a few pathological developments.

In this connection it is only necessary to refer to the views advanced by Travers,[10] Busk,[11] Nunnelly,[12] Morton,[13] Velpeau, and many others, and to note the modification of the names chosen, and the theories advanced, as pathological proofs accumulated.

If, however, the weight of pathological evidence of the earlier cases does not convincingly point to one, but on the contrary upholds a variety of distinct lesions, both intra- and extra-orbital, the results of more recent post-mortem examinations and the careful analysis of the

[9] Pétrequin's was the first fatal case following ligation. It occurred in 1845, and was the first lethal termination among twelve cases which, with the exception of Roux's case, in which no effect was produced on the disease, all proved successful. No post-mortem examination was made in Pétrequin's case.

non-fatal cases assigns to one lesion, rupture of the internal carotid within the cavernous sinus, a foremost consideration. In addition to anatomical proof it offers a most rational and plausible explanation for the clinical phenomena.

Those who first described this rare affection based their diagnosis on clinical interpretation alone, and it was upheld on purely speculative evidence. Only in exceptional instances were post-mortem examination practicable, and unfortunately in these cases (Guthrie,[14] Carron du Villards[15]) only meagre and untrustworthy accounts concerning the clinical manifestations were offered. In Carron du Villards' case, discovered accidentally in the dissecting-room, nothing is known of the symptoms during life. The first cases which were accurately observed and reported, proved so uniformly successful, and yielded so promptly to the treatment instituted, *i.e.*, ligation of the common carotid artery, that the real causative pathological factor was not discovered, and, as already mentioned, only speculative assertions, based on favorite theories as to origin, cause, and nature of the lesion were advanced.

Travers reported the first authentic case in 1809; he chose to designate it aneurism by anastomosis. Doubtless the teachings and classical descriptions of this lesion, in other parts of the body, by Hunter, as suggested by Rivington[16] and other writers on this subject, induced him to select this name for the orbital affection. He was followed by other surgeons, who adhered to the same term. Guthrie observed a most interesting case and described it as one of aneurism by anastomosis. His patient died of some other disease, and no interference was resorted to to relieve the affection of the orbits. Post-mortem examination revealed a true aneurism of each ophthalmic artery. That this pathological discovery would modify the views of subsequent observers was to be foreseen, particularly as the interpretation of the more prominent symptoms appeared so much more rational with the acceptance of this lesion as the causative factor, and also for the reason that for the first time definite pathological evidence was furnished by at least one example. Accordingly, aneurism of the ophthalmic artery was regarded for a number of years as the most probable lesion, but cases were nevertheless described under the first term. In 1835 Baron[17] presented to the Anatomical Society of Paris a pathological specimen of rare interest. It was destined to, and in fact did, modify the until then accepted views. During the life of Baron's patient, exophthalmus, varicosity of the orbital veins, loud bellows murmur, etc., had existed. The patient died of some intercurrent disease. On post-mortem examination an aneurismal dilatation of the internal carotid, which had ruptured into the cavernous sinus, was found. Gendrin[18] reported in 1841 a similar case observed in 1835, in which the same lesion was most probable, although not so conclusively demonstrated by the post-mortem. Two distinct lesions upheld by post-mortem evidence could now be offered as tangible proof to account for and explain the clinical features; in addition the hypothetical ones, aneurism by anastomosis, erectile tumor of the orbit, etc., also continued to maintain their claim.

Out of the entire list of one hundred and thirteen cases only three unquestionable cases of aneurism of the ophthalmic artery, two of these within the orbit and one near its origin from the carotid, have been verified by post-mortem examination. In two additional cases an aneurism appeared the most probable conclusion; in the first (Dudley[19]) it was intracranial, and in the second (Williams[20]) case it was orbital. Both cases recovered. Dudley ligated the common carotid, and Williams resorted to instrumental compression. This last case is not included in Mr. Rivington's or Professor H. Sattler's list of cases.

In 1855 Nélaton[21] met with an exceptional case. His patient, a young student, received a blow with an umbrella against the left orbit. Two months later, the wound having completely cicatrized and vision good on the left side, exophthalmus, ptosis, pulsation of the globe developed on the opposite or right side. Compression by means of a tourniquet and other measures were tried, but the patient succumbed to uncontrollable hemorrhage three months after the accident. Post-mortem examination revealed a fracture of the sphenoid and a rupture of the right internal carotid in the cavernous sinus produced by a splinter of bone. In 1865 Nélaton observed another and similar case. A young girl was thrown from a wagon with resulting fracture of the skull. Marked exophthalmus, visible pulsation of globe, loud bruit existed eight months afterward. Digital compression of the carotid was first tried, but was ineffectual, and was followed by ligature of the common carotid artery. The patient died amid symptoms of pyæmia. Post-mortem examination disclosed enormous dilatation of the ophthalmic veins, and a rupture 2 mm. in diameter of the internal carotid and communication with the cavernous sinus; a fracture of the sphenoid and a detached splinter of bone which had produced the rent.

The anatomical alterations found in these two cases, and in one reported by Hirschfeld[22] in 1858, again called attention to the remarkable case reported by Baron. During all these years this case was not appreciated in all its importance, or considered as possibly offering the most rational anatomical basis and explanation for this rare affection. In 1870 Delens, basing his deductions on a most careful and analytic study of the reported cases, and a review of the pathological proofs, again advanced and upheld the probable correctness of Baron's conclusions. He fortified and advanced the latter's views, and suggested in addition to arterio-venous communication, arterial propulsion or direct forcing of the arterial current into the venous channels of the orbit.

Even though at present the pathological evidence, that arterio-venous communication and arterial propulsion constitute the real lesion, is not sufficiently numerous, convincing, or conclusive, it nevertheless rests upon a more secure anatomical basis than all the other lesions or imperfectly supported theories.

True aneurism of the ophthalmic artery,[23] spontaneous rupture of an aneurismal dilatation of the internal carotid within the cavernous sinus,[24] traumatic rupture of the internal carotid and arterio-venous communication between it and the cavernous sinus,[25] thrombosis of the cavernous and petrosal sinuses,[26] (?) and tumors of the orbit[27] are the pathological alterations verified and upheld by post-mortem examination. Aneurism by anastomosis, the favorite term selected by so many surgeons, has never been confirmed by post mortem examination.

Out of 113 cases described under various names, but all presenting to a greater or lesser degree the more conspicuous clinical symptoms, 26 fatal cases are recorded. Post-mortem examination was made in 19.

Unmistakable rupture or perforation of the internal carotid and communication with the cavernous sinus was discovered in four cases, all traumatic. The first is the celebrated case of Nélaton (1855), the second is Hirschfeld's (1858), the third is Nélaton's second (1865), and the fourth is Leber's case (1878). In these four instances post-mortem examination definitely established a rupture of the internal carotid within the sinus. In Nélaton's first case it was produced by a splinter of bone and fracture of the sphenoid, etc. The artery was extensively

ruptured and torn transversely. In Hirschfeld's patient, an old woman, a small circular rupture was found in the internal carotid. Nélaton's second case was equally conclusive; a splinter of bone was found driven through the wall of the sinus into the internal carotid. Leber's case showed marked dilatation of the internal carotid and several small openings communicating with the sinus.

Spontaneous rupture of an aneurismal dilatation of the internal carotid was first described, and the pathological specimen produced as proof, by Baron in 1835. A second case was observed by Gendrin in the same year, but reported six years later, in which a similar lesion was probable, though not so conclusively demonstrated. A third case was described by Nunnelly; death occurred on the sixteenth day following ligation.

For more complete reference to this case I must refer to Nunnelly's[28] description, and for additional and exhaustive information, to the excellent and complete monographs by Mr. Rivington[29] and Professor H. Sattler.[30] The latter is a German authority upon this interesting subject, and the author of a most exhaustive and analytic article, containing a tabulated statement of one hundred and six cases. In either one will be found an accurate compilation of the reported cases and also a most thorough review of the prominent symptoms and special features of interest of the more remarkable cases.[31]

In five additional fatal cases arterio-venous communication was most probable, even though it was not definitely established by the post-mortem examination which was made in every case. These five include Blessig's interesting case, in which a dilatation of the internal carotid within the cavernous sinus was found; a perforation of its wall could not, however, be demonstrated. De Wecker and Richet's case may also be considered one of arterio-venous communication; the rent in the artery so small, however, that it was overlooked. Bowman's case, reported by Hulke, is replete with interest. No arterial lesion was found, but extensive thrombosis of the cavernous circular and transverse sinuses existed. This case elicited much discussion. In one of Morton's cases the post-mortem examination was made under great difficulties. It is stated that great dilatation and plugging of the cavernous and circular sinuses was found, but no arterial lesion. The fifth, observed by Von Oettingen, is interesting because the pulsating exophthalmus disappeared, either spontaneously or as the result of local depletion, compress bandage, and digital compression. Two years afterward the patient died. The orbital lesion was supposed to have been due to a thrombosis or partial obliteration of the ophthalmic veins, and traces of a localized inflammation of the periosteum and retro-bulbar cellular tissue were found.

True aneurism of the ophthalmic artery was found in three cases—in Guthrie's and Carron du Villards' cases within the orbit, and in Nunnelly's at or near its origin from the carotid.

A tumor of the orbit was found in three cases. In Nunnelly's and Lenoir's cases it was malignant; in Oettingen's it was fibrous.

To the large list of so-called "pulsating cancer of the orbit," Critchett, Nunnelly, Halstead, Mott, Van Buren, Hamilton, and others cited in Noyes' article,[32] I can add another case. In 1880, a boy was brought to my clinic with exophthalmus and the existence of an elastic and soft projection at the inferior margin of the orbit. The tumor was elastic, and could, with pressure, be made to recede; no bruit was heard, but distinct pulsation was felt over the tumor. Compression of the carotid arrested it. The existence of this symptom made the diagnosis of pulsating angioma tenable; but the future rapid progress of the growth, and with it disappearance of the pulsation, dispelled all doubt concerning its nature. I removed the tumor, a myeloid sarcoma, without sacrificing the globe. For several months no return was noticed, and then followed a most rapid increase. Complete extirpation of the orbital contents and the use of the thermo-cautery accomplished a brief interval, but renewed activity soon followed and the boy succumbed, secondary manifestations occurring in the brain, the bones, and other organs.

Accepting, then, as the most probable lesion—rupture, large or small, traumatic or spontaneous—of the internal carotid, communication with and arterial propulsion into the cavernous sinus and its tributaries, the following concomitant conditions and symptoms may be considered manifest phenomena:

1. As a result of the rupture, a direct propulsion of the arterial column into the sinus, depending in volume and force on the dimensions of the rent, will occur; this will also bring about an interruption in the physiological current or afferent function of this principal venous channel and its tributaries. This again entails interference and impediment, and may result in complete suspension and even a reflux or forcing back of the venous currents. The veins are transformed into distended, tortuous, pulsating channels, with dilated fusiform, glove-finger-like prominences in the anterior portion of the orbit, at points where the palpebral veins pass through the septum orbitale into the larger divisions of the ophthalmic veins.[33] These pulsating, smooth, elastic prominences[34] are therefore found just beneath the margin of the orbit, notably in the upper and inner region, and in some cases they even project beyond it. In many instances visible pulsation exists; in others a simple stretching of the skin toward the nasal or temporal side renders it visible. On palpation a distinct impulse is communicated to the finger. Its force will vary: in the majority of cases it is strong, and again in others it is very feeble.[35] It will be influenced by physical exertion and the existence of a cardiac lesion. Localized absorption of the bony margin in consequence of the forcible pulsation is not an infrequent occurrence. In Brainard's case, 1851, reported in *The Lancet*, 1853, vol. ii., p. 102, it was pronounced. In the present case, it had unmistakably resulted, but was not very pronounced.

2. The obstruction, arrest, or reflux to the flow of blood from the orbit through the cavernous sinus, causing, as already mentioned, distention and the pulsating bossy protuberances of the larger tributaries, the venæ ophthalmic, superior and inferior, must also sooner or later result in dilatation and tortuosity of the tributary veins of the latter, which collect the blood from the terminal venous territories of the palpebral area. The veins comprising the terminal superficial territories become tortuous and dilated, with a distention and mound-like elevation of the entire palpebral area, which may extend also into the adjoining temporal, frontal, and nasal regions. This is typi-

[28] Nunnelly: Op. cit. [29] Rivington: Op. cit.

[30] Sattler, Professor H.: Pulsierender Exophthalmus. Graefe and Saemisch: Handbuch der gesammten Augenheilkunde.

[31] W. Rivington, p. 218, op. cit., refers to a remarkable case of Mr. Holmes'. His patient, a boy, aged sixteen, died of heart disease; at the post-mortem examination aneurism of the left internal carotid artery about the size of a small nut, filled with laminated coagulum, was found at the anterior part of the cavernous sinus. The third, fourth, and fifth nerves were stretched by the tumor. During life the orbital symptoms had been ptosis, dilated and fixed pupils, diplopia, impaired vision, and uncertainty in the movements of the eyeball. [Mr. Hutchinson communicated to the Clinical Society, after this paper had been read, a most interesting case of a circumscribed sacculated aneurism springing from the outer side of the left internal carotid artery in the cavernous sinus, and communicating with the carotid by a small aperture. The patient was a female, forty years of age. The tumor was as large as a pigeon's egg, and occupied the middle fossa of the skull. It appeared to have obliterated the cavernous sinus. There had been no orbital symptoms during life, except those due to pressure on the third, fourth, and fifth nerves (Lancet, April 17, 1875).]

[32] Noyes, quoted by Mr. Rivington, p. 230, op. cit., and New York Medical Journal, 1869.

[33] Aubry in 1853 reported an interesting case, and to him belongs the credit of having established that the orbital veins may be transformed into pulsating channels. His patient, a woman, died suddenly after admission to the hospital. The post-mortem examination revealed no arterial lesion, but great enlargement of the ophthalmic veins. They and their terminal tributaries had formed the elastic vascular pulsating tumors. The cavernous sinus was enormously dilated, and communicated freely with the varicose ophthalmic veins, and terminated behind in a cul-de-sac, the communication with the inferior petrosal being cut off.

[34] A reference to the traumatic cases compiled in W. Rivington's paper and the tabulated list of Professor H. Sattler will afford abundant illustration of this prominent symptom.

[35] Compare case reported by W. Adams Frost, Pulsating Exophthalmus with Observations, Transactions of the Ophthalmic Society of the United Kingdom. "In the left orbit the swellings were soft and compressible and pulsated in a gently distensile manner. On the right side a globular swelling larger than a pea; it was soft and reducible and pulsated feebly."

cally indicative of obstruction situated in the ophthalmic veins or cavernous sinus. It is only in part due to the proptosis; its real explanation is the distention of the terminal venous ramifications. The upper lid is its principal seat; the skin presents a dusky red appearance, traversed by prominent and tortuous veins. The superficial veins may become so prominent that feeble pulsation and a distinct thrill or purr can be discovered on palpation.

3. The same cause, obstruction to the exit of blood from the orbit, also causes another typical symptom—proptosis and spontaneous and visible or easily producible pulsation of the prominent globe. In many cases the pulsation of the eyeball can only be detected by pressing the fingers over the closed lid; even slight pressure will discover a more or less forcible impulse.

4. Additional results from the same cause are disturbances of the intra-ocular circulation and impairment or suspension of function of the eye, paralytic phenomena of the motor and sensory nerves of the eye and appendages.

(To be continued.)

Progress of Medical Science.

Cysticercus in the Vitreous.—Don Pedro Lagleyze describes, in a Buenos Ayres medical journal, a case of cysticercus in the vitreous, this being the only recorded instance of an interocular entozoon occurring in the Argentine Republic. The patient was a man thirty-four years of age. Six months before his eye-trouble commenced he had passed a tape-worm. The first symptoms were pains in the supra-orbital arch and flashes of light in the right eye, the power of vision of which rapidly deteriorated. A month after these symptoms commenced he noticed that the vision of the left eye was beginning to be impaired; he therefore consulted a medical man, who treated him for more than a year before he was admitted to the hospital at Buenos Ayres, under the care of Dr. Don Cleto Aguirre. There was no injection of either conjunctiva; pupils sluggish, vision much impaired. Left eye: fingers scarcely counted at fifteen centimetres, tension normal, atrophy of papilla. Right eye: an extensive hiatus in the superior half of the field of vision, central vision one-seventh, tension greatly diminished. With the reflector a characteristic cysticercus was seen in the vitreous, with two suckers visible, but not the corona of hooklets; it was dead, but apparently had not been long so, for about a month afterward there was a considerable change, the head having become globular and the neck shrunken. The body, which had been translucent, and therefore appeared red by the transmission of rays from the fundus, was now opaque. The retina was detached at the point where the animal pierced it. The papilla was white, as in the left eye, this being not due to the entozoon, but merely a coincidence. The atrophy continued to increase in spite of remedies.—*The Lancet*, May 2, 1885.

Nervous Colics.—Dr. Cherchevski calls attention to a group of symptoms which he has observed, especially in persons whose work taxes the mind and who are anæmic or debilitated. Such persons are habitually constipated, and have abdominal enlargement and noisy eructations without anorexia. Now and then, under the influence of prolonged intellectual labor or emotion, this condition is aggravated suddenly. Enormous meteorism develops, there is superficial respiration, shortness of breath, cyanosis, pains sometimes fixed at the site of the liver, or in the umbilical region, sometimes shifting about, then a sense of weight at the pit of the stomach with a violent tenesmus. The attack ends in a few days, with abundant evacuations. On the approach of the crisis the excreta take on a ribbon form, as if there were a stricture of the intestine. The author regards these phenomena as due to a disturbance of the nervous system, producing a localized intestinal spasm in the circular fibres of the muscular tunic. He thinks this is demonstrated by the action of medicines, since in these patients purgatives increase the pain and constipation, while opium and belladonna relieve both the meteorism and the other symptoms.—*St. Louis Courier of Medicine*, May, 1885.

Contribution to the Doctrine of Spinal Ataxy.—Professor Erb remarks that locomotor ataxia is still the subject of animated discussion. There are three views current among neurologists. Some hold that ataxy depends on disturbances of the sensibility (sensory ataxy); others attribute it to a disturbance of centrifugal "coordinating" tracts (motor ataxy), and a third party believe it to be due to a lesion of supposed tracts between sensory and motor apparatus, serving to transmit the reflexes and to regulate the movements. Erb discards the latter theory. As regards the first, he admits that the degree of ataxy is certainly influenced by disturbances of sensibility (sensory control), but the sensory theory becomes untenable, if it can be shown that cases occur in which: 1. Spinal sensory disturbance of a high degree exists without any ataxy. 2. If clear spinal ataxy exists without any demonstrable sensory disturbance. Erb describes a case of the second class, spinal ataxy without disturbance of sensibility. The case is one of ataxy without tabes. The patient is fifty-two years of age. No syphilis or alcoholism. Debility and instability in the lower extremities since three years. No diplopia, weakness of bladder, vertigo, vomiting, occipital pain, or thoracic constriction. There is marked ataxy. Sensibility of skin and muscles normal. Cutaneous and tendon reflexes normal. No cerebral symptoms. It is difficult to locate the lesion, but it is evidently a case of spinal ataxy without simultaneous sensory disturbance. The conclusive proof of the independence of ataxy of sensory disturbance would be the demonstration of a case of spinal anæsthesia without ataxy.—*The Alienist and Neurologist*, April, 1885.

A Study of Antipyrin.—Dr. Arduin has published (*Bulletin Général de Thérapeutique*, March 30, 1885) an interesting study of the physiological action and therapeutical indications of antipyrin. He gave the drug in various ways, by the mouth, by the rectum, and subcutaneously. The usual oral exhibition of the drug, he finds, is the best. The dose varies with the disease, but should not be less than six grains nor more than forty-five per diem. He believes that more than fifteen grains should not be given at a time, but this dose may be repeated every hour for three hours. The author formulates the following conclusions: 1. In febrile diseases pyrexia is not properly an indication for the exhibition of febrifuge remedies; but any exaggeration of "the febrile movement, *i.e.*, hyperthermy," does constitute an indication for the employment of such medicaments. 2. In the great pyrexias like typhoid fever, in wasting diseases like pulmonary phthisis, any continuance of pyrexia should be met by the employment of febrifuge remedies, notably antipyrin. 3. The drug should be given in moderate doses frequently repeated, in order to avoid profuse perspiration and the induction of adynamia. 4. One should not expect of this remedy and other antipyretics more than it is possible to do in accordance with physiological laws. In other words, one should not expect to be able to transform a grave malady into one running its course without fever.

A Medical View of Army Morals.—Whenever a case of scrofulous disease was presented at his clinic, in the person of a child *whose father had been in the army*, the late Professor Gross, asking no further questions, would turn to the class with the single, but significant remark, "*Specific*, gentlemen!"—*Col. Med. Journ.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 13, 1885.

THE ORGANIZATION OF THE INTERNATIONAL MEDICAL CONGRESS.

IN the *Journal of the American Medical Association*, for May 30th, Dr. Davis gives editorially an elaborate and lucid review of the situation as regards the organization of the next International Medical Congress. Dr. Davis concedes at once, and with somewhat surprising readiness, that the original organizing committee made three serious mistakes, viz., in allowing gentlemen who have expressed themselves in favor of the New Code representation on the committee; in not giving a proper geographical representation in the official organization; and in publishing the results of the committee's work before reporting to the American Medical Association. Dr. Davis appears to admit that the original committee did not have "full power," although it is specifically so stated in the resolution, but was still the creature of the Association. He practically concedes, therefore, all that one of the truthful apostles of the present disturbance—Dr. Shoemaker, of Philadelphia—claimed; and charges his colleagues with having committed errors "of judgment, not of design."

The remedy for the present trouble is seen by Dr. Davis in the committee appointed by the Association at its last meeting. The resolutions appointing this committee of thirty-eight, add its membership to that of the original seven, making the present committee forty-five. These resolutions at the same time eliminate, according to Dr. Davis, the fifteen or twenty additional members appointed by the original committee of eight. Thus, we are assured, the matter is nearly all settled. The objectionable fifteen or twenty added to the first seven are eliminated, and the new forty-five can go to work afresh.

Perhaps this view may prove practically the best solution of the present problem. If so, if it can be adopted legally and fairly, so that the organization of the Congress can go on, we shall be heartily glad. Nothing will be more mortifying to those who have the welfare of the profession at heart, than to be obliged to expose to our European Congress a quarrelling and disorganized profession.

It is certain, however, that Dr. Davis is mistaken in one point. He says: "There is nothing in the resolutions quoted [appointing the New Orleans committee], or in any other action of the Association during the meeting in New Orleans, that directly destroys the previous official organization of the committee, or nullifies a single item of the work already done toward organizing the Congress."

This is not an ingenuous or a correct statement. The second of the resolutions referred to does, *indirectly*, destroy the previous official organization. It says that said committee of thirty-eight is "hereby authorized and empowered to select a chairman and secretary, to fill all vacancies that may occur by death or inability to attend the committee meetings, and to *appoint the officers of the Congress.*"

Now, since the officers of the Congress were already appointed, and known to be appointed, the above clause certainly does destroy and nullify work already done by the first committee.

Furthermore, if the resolutions, as interpreted by Dr. Davis, do "eliminate" the additional members added by the first committee, in so doing they also "nullify," and even directly destroy the work of that committee. It was part of this committee's work to enlarge its membership.

The appointment of the New Orleans committee, according to Dr. Davis, sets aside this work; and yet we are told at the same time by him that "it does not nullify a single item of the work already done."

The reasoning of our esteemed colleague is thus shown to be plainly and exquisitely illogical. Whether it may not be expedient, however, to adopt his suggestion and interpretation is another matter. It rests with the original (enlarged) committee to say whether they will, for the good of the cause, accept decapitation and revision at the hands of the thirty-eight.

One thing, however, is certain, beyond doubt or cavil, viz., that any dragging of the Code question into this matter is unnecessary, and will create more trouble than all of the other issues together. A policy, which would remove the president of the New York Academy of Medicine, and substitute any ambitious agitator from a neighboring city, for example, would be received with a storm of indignation not only in New York, but throughout the country. The Code has no more to do with the International Medical Congress than the laws of Buddha with the climatic treatment of phthisis. The Medical Congress is a scientific body. It should be composed of medical men, of whom one asks nothing but that they have ability and honesty. The American Medical Association numbers but a minority of the profession of the country. It has no right to thrust its by-laws in the face of strangers, or to force a dispute over etiquette into a prominence which will make American physicians ridiculous in the eyes of the world. The gentlemen who will come to us from Europe know something of morals and manners, but nothing of "Ethical Codes."

THE BOSTON MIND-CURE.

BOSTON has come to the conclusion that as "a man thinketh, so is he." If he *thinks* he is sick, he is sick, very sick. The cure for this is to think he is well, and presto! he *is* well. This, as far as we can find out, is the sum and substance of the mind-cure. New York need not be jealous that Boston discovered this wonderful thing. New York is given over to money-making irretrievably, it is to be feared; while Boston is given over

to psychics, including all the phases of thought-transference, mind-reading, and the like. What wonder that metaphysical medicine makes a stride in this hot-house air? Pagan Boston—and it is now fashionable to be a pagan in Boston—endorses as heartily "the mind-cure" as a portion of Christian Boston supports the faith-cure.

In Boston classes are formed and educated in the mind-cure. To practise it one must be truly high-minded and free from all moral taint. The *modus operandi* is exceedingly simple. The patient takes a seat alone in the room with the mind-curer, who sits at some distance from the individual, not looking at him or regarding him. To mix up mesmerism, magnetism, or hypnotism with "the cure" is very reprehensible, and not to be allowed. The sittings are fifteen minutes in length, and the fee two dollars. The latter may seem a minor consideration; still there are those who will like to know at what rates one may charge for the mind pure and simple, unadulterated with prescriptions or drugs.

The following cases are vouched for as true instances of cure effected by the mind:

A woman with angina pectoris, so diagnosticated by several prominent physicians, was cured at one sitting with Boston's most famous and original mind-curer.

A gentleman had his feet frozen, having lost his way in a fearful snow-storm last winter. His physicians advised amputation. His wife had been in the classes formed for instruction in the mind-cure. Why not try it in this instance? she thought. She, her husband, and Boston were electrified with the result, which was complete recovery.

A woman suffering with obstinate constipation, and insanity which caused her incarceration in a retreat for a long time, was subjected to the influence of the mind-cure, with the result of a perfect restoration.

These cases seem remarkable; but how much more so the following: A young lady was much prostrated with debility and trouble with the eyes, yet she was so intolerant of faith-cures and mind-cures that her friends, believers in this new psychic therapy, did not dare to broach to her the question of making a trial of it. They induced a mind-curer to come and endeavor to restore her while she was asleep, and thus unconscious of the attempts. This was done, and anon the young lady improved astonishingly.

One is powerless to make comments in such cases as these. Surely, the last cure represents a wonderful swinging of the pendulum in Massachusetts in the century or so which has elapsed since the "evil eye" of Salem witches did such dreadful work. Now, if one sits with benevolent thought intent with the sick, lo, a wondrous healing is wrought.

A tract, written by one of the busiest of the practitioners of this kind of healing art, is before us, in which is epitomized in a remarkable manner the method of the mind-cure:

"It is in the realization of the absoluteness of the Real, and ephemeral nature of the Unreal, that we do our work."

Again we quote, for it is by using the words of the exponents of the theory that one can acquit himself of accusations of exaggeration and misrepresentations.

"In the case of a cold sore on the lip, one must separate the natural thought from the spiritual, not necessarily in these words, but in some way to make the distinction marked between the Real and the Unreal, the free and universal mind and that which is trammelled and entangled in the yoke of bondage.

"The natural mind will bring the thought of throbbing and beating that inflammation asserts itself with; the cause will come also as cold. The spiritual mind will bring the thought, 'What is there in my lip to have inflammation?' One must realize there is nothing there but life. All life flows from the infinite fountain of life, is perfect, and not subject to atmospheric changes; therefore the lip cannot have inflammation. One must realize that it cannot exist if not nourished.

"Now, being a free agent by one's will, he chooses the free, real perfect mind, and says to the other thought, 'I have no sympathy with you, I do not desire you, you cannot assert yourself to my mind; for I am the recipient of infinite intelligence, and know you are only an appearance, have no reality in you; for if you were real, you would be eternal and never disappear.'

"You become separated from it, and mind, which is infinite, controls all things."

It is true that nearly all physicians recognize the powerful effect of the mind over disease, but certainly not to this extent. Time only can show to what proportions the mind-cure, pure and simple, will come, or whether, like planchette and blue glass, it will have its day shortly and become a matter of the past, a curious phase of human thought, the ephemeral product of the hour.

CONTAGIOUS OPHTHALMIA IN THE ORPHAN ASYLUMS.

The report on contagious ophthalmia in the orphan asylums of the city, which is printed elsewhere in the columns of The Record, is worthy of careful attention. It appears that there are asylums in this city, containing from two to five hundred children each, one-half of whom have a disease of the eyes which is dangerous to the sight, and to a very marked degree contagious. In many of these asylums children are received who are already afflicted with this disease, and these children become members of a household which contains those whose eyes are well. In the overcrowded institution it is not strange that new cases of contagious ophthalmia occur, and it is a matter of record that the eyes of inmates of these asylums are lost. Here is a disease which destroys as many eyes as scarlet fever or diphtheria together destroy lives of the same children. The statistics which Dr. Derby presents show that of the children examined in twenty-four asylums 19.19 per cent., or one in every five, had this disease. To meet an evil so great as this, prompt and efficient measures must be taken, and the action of the Academy on Thursday last we heartily approve. A committee, consisting of members of the State Board of Charities, State Charities Aid Association, and the Society for the Prevention of Cruelty to Children have been invited to confer with the Council of the Academy to formulate a plan of lessening the prevalence of this grave disease. To us it seems that no more urgent work could be undertaken, and the address of Mr. Gerry at the Academy meeting is an earnest that the health and

future happiness of the children cared for by our city institutions shall no longer be jeopardized as it has been in the past.

An inspection of every asylum should be made, and a statement rendered to the Board of Health of the number of cases of communicable eye disease within its walls.

A competent commission of medical men should prescribe treatment and define quarantine laws for the sore-eyed children. No child should be admitted to any asylum without a certificate from a competent authority that his or her eyes are sound.

This report to which we have referred shows a condition of things that is a disgrace to our civilization. That the little children for whom our courts and charitable societies provide shelter and food should be collected in large numbers in institutions where one out of every five is likely to acquire, and does acquire, a disease which may be a life-long burden, is without a parallel and calls loudly for relief.

News of the Week.

Dr. Barstow entertained the members of the Medical and Surgical Society at Sanford Hall, Flushing, on Saturday, June 6th.

The Plymouth Epidemic.—Dr. J. L. Rea, of Scranton, Pa., writes: "I would like to ask Dr. Torrey why he neglected to state in his paper on the Plymouth epidemic, in last week's Record, that among eight hundred persons living in a suburb of Plymouth, who are supplied with water entirely from the Susquehanna River by the Delaware & Hudson Canal Co., there has not been a single case of the disease? Also, why he did not state that among those who used well-water upon one side of a street, there were no cases, unless they also drank of hydrant-water; while on the other side of the street, where hydrant-water was used, almost every house was afflicted? These are well-established *facts*. Why ignore them? If the river-water is so vile, why do not a dozen other towns along its banks, who use the water, have a Plymouth epidemic?"

Oregon State Medical Society.—The twelfth annual meeting of the Oregon State Medical Society was held at Portland, Monday, Tuesday, and Wednesday, June 8, 9, and 10, 1885.

The American Neurological Association will hold its eleventh annual meeting in the Hall of the Academy of Medicine, 12 West Thirty-first Street, New York, on June 17th, 18th, and 19th.

American Laryngological Association.—The seventh annual congress of the American Laryngological Association will be held in Abstract Hall, Lafayette Avenue, Detroit, Mich., June 24, 25, and 26, 1885. The profession is cordially invited to attend the sessions of the congress.

The Michigan State Medical Society held its twentieth annual meeting during the past week, at Port Huron, commencing at 10 A.M., Wednesday, June 10, 1885.

The University of Pennsylvania and the Jefferson Medical College have each discontinued their post-graduate course.

The Medical School of Maine held its annual Commencement on May 27th, when a class of fourteen was graduated. A movement is on foot to move the school to Portland, where it will have better clinical facilities.

The Long Island College Hospital held its twenty-sixth annual Commencement on June 3d. A class of forty-seven was graduated.

Death of Dr. McChesney.—Dr. Jacob N. McChesney, a Sanitary Inspector in the Fourth Sanitary Division of the New York City Board of Health, died at Staunton, Va., last week of consumption. Dr. McChesney, who was the son of an eminent physician, was born at Staunton. He was educated in the Washington and Lee University, and the University of Virginia, and was graduated at Bellevue Medical College in 1874.

Dr. Hiram Moses, Sr., the oldest physician in Rensselaer County, died on June 4th. He was graduated from Yale College in 1825, and had practised medicine in Rensselaer County for fifty years.

The Late Dr. Jacob Newton McChesney.—At a regular meeting of the Manhattan Medical and Surgical Society, held June 6, 1885, the following preamble and resolutions were adopted:

Whereas, It has pleased an all-wise Providence to remove from our midst our friend and colleague, Dr. Jacob Newton McChesney. Be it, therefore,

Resolved, That this Society and the medical profession have sustained the loss of a most active, earnest, and useful member.

Resolved, That we his associates mourn the loss of a warm-hearted and faithful friend.

Resolved, That we extend to his bereaved family our sincere sympathy in their affliction.

Resolved, That on a page in the minutes of this Society be inscribed his name, and the dates of his birth and death, and that these resolutions be published in The Medical Record and the Virginia *Medical Journal*, and that a copy of them be sent to his family.

(Signed) Chas. W. Allen, M.D.,
T. T. Gaunt, M.D.,
A. M. Leon, M.D.,
Wm. S. Seamans, M.D.,
Committee.

The Richmond County Medical Association held a special meeting last week, to express their indignation about the present condition of the cells at the County Almshouse, where insane paupers are placed when under confinement. A committee consisting of Drs. Van Rensselaer, Wood, Walser, and Feeney, was appointed to further investigate the abuses complained of and secure a prompt remedy if possible.

Medical Laws in Texas.—We stated several weeks ago that there was no law regulating the practice of medicine in Texas. We should have said, no efficient law. Any man who has a medical diploma, bogus or otherwise, can practise, by registering himself with the County Clerk.

THE MARCH OF THE PESTILENCE.—The cholera has spread from the southeastern provinces of Spain to Madrid. It has appeared with the greatest violence in Valencia. It is stated on newspaper authority that the cholera appeared in Spain last winter at Jativa, whence it spread westward to Malaga, and eastward to the Balearic Islands. Up to the middle of May the number of cases was estimated at about four hundred, with about one hundred and forty deaths.

SMALL-POX is very prevalent in London, where there are said to be fifteen hundred cases. A number of cases have been observed among the immigrants brought to this port. Montreal is seriously threatened with this disease. The Chairman of the Board of Health announced on June 5th, that small-pox was epidemic in the northeastern district, and that it had got beyond the control of the Board. The health officers are greatly hindered by the people doing all they can to hide the cases that exist in their houses. Small-pox is very prevalent in German ports, and in France on the Swiss frontier.

BRITISH MEDICAL ASSOCIATION.—The fifty-third annual meeting of the British Medical Association will be held at Cardiff. on Tuesday, Wednesday, Thursday, and Friday, July 28, 29, 30, and 31, 1885, James Cuming, M.D., F.K.Q.C.P., of Belfast, President; W. T. Edwards, M.D., F.R.C.S., of Cardiff, President-elect. An address in Therapeutics will be delivered by W. Roberts, M.D., F.R.S. An address in Surgery will be delivered by John Marshall, F.R.C.S., F.R.S. An address in Public Medicine will be delivered by Thomas Jones Dyke, F.R.C.S.

THE "LANCET" ON THE ORGANIZATION OF THE INTERNATONAL MEDICAL CONGRESS.—From the reports of the discussion at the meeting of the American Medical Association, "we gather," says the *Lancet*, "that some members of the Association consider that the appointments in the Congress should be filled up on a geographical basis, each State being considered as a distinct entity to be represented. We trust, however, that the new committee will take a wider and more enlightened view than that. and will make the appointments solely in reference to the merits of the various nominees and the degree to which they possess the confidence of the profession in the United States, as a whole, and in Europe. We may be permitted to assure our American brethren that visitors from Europe will in a large measure judge of the position and character of the profession in the States by the scientific eminence of those whom they choose as their prominent representatives."

MEDICAL LAWS IN CALIFORNIA.—A correspondent asks regarding the medical laws of California. He will find full details in the pamphlet on "Medical Education," published by the Illinois State Health Board in 1883. California has a medical law which creates three Examining Boards. All persons intending to practise medicine must submit their diplomas to one of these boards. The law is not regarded with much favor by the profession of the State.

QUACKS FALLING OUT.—A great misfortune has fallen upon a family of quacks, father and son, who appeal daily to erring and exhausted, but noble, readers of the public press. Another quack has taken the name of the son, and is doing a fine business in Salt Lake City. The parent of Dr. Quack, Jr., has had to go West and assure the people that he is father of the real and only curer of all andrological diseases (we thank the Boston *Medical and Surgical Journal* for the word).

THE INTERNATIONAL SANITARY CONFERENCE.—"The discussions which have already taken place among the technical expert delegates at the International Sanitary Conference at Rome have," says *The British Medical Journal*, "revealed the fact that even the nations which formerly most relied on quarantine are beginning to understand that quarantine is useless. Turkey is now the only country which maintains that sanitary cordons and quarantine on land-routes are useful measures. With regard to maritime quarantine, there is not the same unanimity, though the chief supporters are the Spaniards, Portuguese, and Turks, who have not yet learnt the lesson which experience has often taught them within their own borders. It is understood that, in urging the practical administrative advantages of medical inspection and isolation, the delegates of the British and Indian Governments have had the powerful support of Dr. Koch, the delegate of the German Government, and Dr. Sternberg, the delegate of the United States, and that a resolution proposed by M. Brouardel, the delegate of the French Government, endorsing this principle, has been unanimously adopted by the Conference. The resolution invited the powers interested to construct model ports, and to provide for a rigorous inspection of vessels arriving from infected places. At the meeting on May 27th, a sub-committee, consisting of Dr. Koch, Dr. Thorne, Dr. Sternberg, Dr. Eck, and M. Proust, was appointed to report on the best means of disinfecting ships, public conveyances, and buildings. The report ought to be a valuable document, and will, it may reasonably be hoped, result in a uniform method of disinfection in all countries, so that we shall hear no more of the puerilities which were often noted in these pages last year. A proposal, made by Dr. Sternberg, authorizing consuls to examine the sanitary condition of ships proceeding to ports in the countries which they represent, was negatived by a large majority."

GEORGIA DOCTORS.—The *Atlanta Medical and Surgical Journal* has a portrait-gallery, in which each month there are given cuts of distinguished local physicians and surgeons. The Georgia doctors are able men, but not handsome.

"NEWS OF THE WEEK."—Under this head we copy the following from the *Indiana Medical Journal*: "The Indiana State Medical Society is not a fool."

A STATUE OF BOUILLARD was unveiled on May 16th, in the principal square of his native city, Angoulême, France. Representatives from the Académie des Sciences, the Académie de Médecine, and the Faculté de Médecine of Paris were present.

FRACTURE OF THE BASE OF THE SKULL.—At a recent meeting of the Cincinnati Academy of Medicine, Dr. W. H. Wilder reported a case of fracture at the base of the skull, in which microscopical examination revealed the presence of brain substance in the discharge from the ear. The patient recovered with only a temporary disturbance of the mental faculties.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Fourth Anniversary, held in Boston, Mass., June 9 and 10, 1885.

(By Telegraph to The Medical Record.)

First Day—Tuesday, June 9th.

In the forenoon the members of the Society availed themselves of the usual opportunities to visit the wards and witness operations at the Massachusetts General, City, and Children's Hospitals. At the General Hospital, Dr. J. Collins Warren performed an amputation of the thigh, and showed cases in the wards which were being treated with sterilized cotton-dressing. Dr. Arthur T. Cabot, at the Children's Hospital, performed MacEwen's operation of osteotomy of the femur for knock-knee. He also showed a case of remarkably good results after trephining for epileptic convulsions. The patient, a boy of six years, had had from six to twenty convulsions daily until the operation, after which they were absent. Dr. H. C. Haven also showed an extremely interesting case of abdominal tumor in a boy of nine years.

At the City Hospital a visit was made to the surgical wards, and numerous cases in the service of Dr. C. D. Homans were shown, in which the good results of thorough antisepsis were made evident. A hæmatocele had healed by first intention after thorough curetting, and a similar result had been obtained with a chronic lumbar abscess. Two cases of strangulated hernia successfully operated upon by Dr. W. P. Boller were also shown, and several interesting operations were performed, among them two rhinoplasties by Dr. George W. Gay, and two operations for cataract by Dr. H. W. Williams.

At noon the members met in Huntington Hall, to listen to papers by Dr. George N. Tilden, of Boston, upon "The Pathogenesis of Certain Affections of the Skin;" Dr. Charles F. Withington, of Roxbury, upon "Consanguineous Marriages: Their Effect upon Offspring;" and Dr. James R. Chadwick, of Boston, upon "Labor Complicated with Fibroids."

The meeting then adjourned until 3 P.M.

At 3 P.M. the members again met in Huntington Hall and listened to the following papers. One by Harold Williams, M.D., of Boston, on the "Climatic Treatment of Phthisis." Dr. Williams was followed by Dr. Morton H. Prince, who read a paper entitled, "How a Lesion of the Brain Results in that Disturbance of Consciousness Known as Aphasia." The final paper was read by Dr. Henry R. Stedman, of Roslindale, and was entitled, "The Relation of Insanity to Certain Nervous Affections." The meeting then adjourned.

At 7 P.M. the annual meeting of the Councillors was held in the Medical Library.

During the day there was an exhibit of electrical, and new and original surgical apparatus in the Technology building, particulars of which will be given in the report of to-morrow's proceedings.

Second Day—Wednesday, June 10th.

During the day, as upon Tuesday, there was an exhibition of electrical and new and original apparatus in the Technology Building.

Dr. J. Collins Warren exhibited the apparatus which he had made, after the suggestion of Dr. H. C. Ernst, for the preparation of sterilized cotton, now being used with much success as a surgical dressing in Dr. Warren's wards.

Dr. Vincent Y. Bowditch exhibited and demonstrated the use of

THE PNEUMATIC ASPIRATOR,

devised by Dr. Herbert F. Williams, of Brooklyn, N. Y.

The business meeting was called to order in Huntington Hall, at 9 A.M., by the President, Dr. Charles D. Homans.

The reports of the Recording Secretary, Dr. Francis W. Goss, and the Treasurer, Dr. Draper, were presented.

At the last annual meeting a resolution offered by Dr. Asa Mullett providing for

MORE STRINGENT REGULATIONS REGARDING THE ADMISSION OF CANDIDATES TO THE SOCIETY,

was submitted to a committee to consider yesterday. The committee reported adversely on the resolution, and the report was adopted without debate.

A series of resolutions which have been adopted by superintendents of various American institutions for the insane, petitioning Congress to pass laws

PROHIBITING IMMIGRATION OF DEFECTIVE CLASSES,

were adopted. The resolutions set forth that while these persons who have immigrated to this country since 1847, comprise, with their descendants, but one-eighth of the population, they furnish one-third of the paupers, one-third of the criminals, and one-third of the insane.

The following medical papers were then read, "Cremation in its Sanitary Aspects," by Dr. John O. Marble, of Worcester; "Diagnosis and Treatment of Occipito-posterior Positions," by Dr. William L. Richardson, of Boston; "The Influence of Ovariotomy on Surgery," by Dr. John Homans, of Boston.

Dr. Marble urged

THE NECESSITY OF THE UNIVERSAL ADOPTION OF CREMATION,

and proved its superiority over all other methods of disposing of the dead by a clear exposition of the great evils attendant upon them, referring particularly to the common form of graveyard interment.

Dr. Richardson dwelt upon the great value of

EXTERNAL PALPATION IN THE DIAGNOSIS OF FŒTAL POSITIONS,

and briefly described the method. He then illustrated his method of applying forceps invented for flexing the head in occipito-posterior positions where it has become unduly extended.

Dr. Homans' paper was of great interest, and traced the

PROGRESS WHICH HAS BEEN MADE IN OVARIOTOMY

since it had been first practised in 1809. He showed how out of it many, if not nearly all, of the valuable abdominal operations of modern surgery had grown. He also spoke of the comparative innocuousness of single abdominal incisions, and the future which may be in store for it as a diagnostic and therapeutic measure.

DELEGATES PRESENTED.

The following delegates were presented: Dr. A. B. Worthington, of the Connecticut Medical Society; Dr. Peter Foley, and Dr. W. L. Bates, of the New York Medical Society; Dr. E. S. Albee, of the Vermont Medical Society, and Dr. C. R. Walker, of the New Hampshire Medical Society.

At twelve o'clock Dr. Franklin K. Paddock, of Pittsfield, began the annual discourse, and during the next hour gave an interesting review of the

HISTORY OF WOUND TREATMENT,

and a clear and concise description of the principles and details of the modern antiseptic method, the value and supremacy of which he proved by convincing statistics. Dr. Paddock recognized that, although familiar to those members of the Society who had favorable opportunities for becoming familiar with and practising it, the antiseptic method was not used by many of the members, and by a few, perhaps, was still even regarded with scepticism, he therefore felt called upon on this fitting occasion to urge upon members the necessity and duty of adopting it.

THE DINNER AND THE TOASTS.

Before the meal began, Dr. Amory called the meeting to order, and the Divine blessing was invoked by Profes-

sor Lawrence, of Harvard Divinity School. After dinner Dr. Amory again called the meeting to order, and delivered a short, pleasant address, in which he eulogized the good effect of annual dinners, "where the bitterness of debate is consumed with the food on the tables." Dr. Amory then announced as the first toast, "The Massachusetts Medical Society," and presented to respond to it Dr. Homans, the President.

Dr. Homans congratulated the Society on its growth and its prosperity. He regretted the prevalence of quackery, and remarked that there was no law against it in the State. He alluded humorously to the attempts of adherents of mind-cure to impose upon the credulity and imagination of people, and closed by urging the members of the Society to stand fast for

CORRECT PRINCIPLES OF PRACTICE.

He was frequently applauded in the course of his remarks.

The Chairman read a letter from Governor Robinson, and then introduced to respond for the State Dr. Walcott, of the State Board of Health. He was received with three rousing cheers, followed immediately by three more. He alluded to

THE OLD BOARD OF HEALTH,

and said that the present conglomerate body grew out of considerations personal and political. It first did some good work, but one thing and another had

DRIVEN GOOD MEN FROM THE BOARD.

To-day only two members out of nine were practitioners of medicine, and the Committee on Lunacy was made up of men without any technical knowledge of the subject. The Board had, however, secured the passage of a law against

THE ADULTERATION OF FOOD AND DRUGS.

Massachusetts was the only State in which these laws were systematically enforced. He said his position on the Board had been unpleasant to him personally, but he had been sustained by the confidence of the members of his profession. He spoke a kind word for his successor, and said he had no reason to doubt that he would be equal to his duties.

Dr. St. John Roosa, of New York City, was introduced as from a city twice as dirty as Boston, and requiring four times as many doctors. He said the city had been clean before the Yankee invasion. He did not pretend to represent officially his New York brethren, but appeared as a private citizen to speak his own opinions. The Medical Society of the State of New York stood with erect banners, ready to do its duty to the people whom it served. It had resolved it should remain a matter of individual responsibility whom allopaths should assist with advice, and where they should go. The medical profession of New York had no quarrel with the American Medical Association, but the constitution of the latter rendered it impossible that it should legislate for the profession in several States. It ought to be a meeting for the fraternization of medical men, a national convention. But its varying character and composition precluded it from being a proper body to establish rules of discipline. The question in New York was not as to the propriety of consulting with homœopaths and eclectics, but

HOW TO RAISE THE STANDARD OF MEDICAL EDUCATION

so high that there would be no no homœopaths, allopaths, or eclectics. The way to bring this about was by a Board of Medical Examiners, independent of the teachers in the different schools. There must be some such tests as in the Army and Navy. The question of medical attainment and education must be put in the foreground, and then distinctions of schools would perish from th earth. The message which the speaker would leave would be that medical men of this great Commonwealth should stand by those of New York in opposition to quackery and in favor of a

HIGH STANDARD OF PERSONAL CULTURE.

Dr. Henry W. Williams, ex-President of the Association, was received with eager applause. He spoke of the importance of the eye and the wonderful advances in the knowledge of it during the year. Dr. Koller of Vienna had discovered a means of suspending sensibility in the eye, a discovery barely second to that of the anæsthetic properties of ether. So important a discovery was worthy the attention of medical men, and ought to win gratitude for its author.

Representative Frederick P. Greenhalghe spoke upon the

ILLITERATE PHARMACY BILL

and the bill to regulate the practice of medicine in the State.

Mayor O'Brien responded for the city, and gave some interesting statistics in regard to the sanitary improvements and expenditures during the last fifteen years.

Senator Marden, of Lowell, delivered a humorous address, and assured his support for the "Doctors' Bill" in the Senate.

Col. Charles H. Taylor was the concluding speaker, and at 3.30 the company dispersed.

ONTARIO MEDICAL ASSOCIATION.

The Fifth Annual Meeting of this Association was held in London, Ont., on June 3 and 4, 1885. The number of physicians in attendance exceeded one hundred and thirty, and thirty-one papers were upon the programme.

The general officers were: Dr. Worthington, of Clinton, President; Drs. Tyce, of Chatham, Thorburn, of Toronto, and Brouse, of Brockville, Vice-Presidents; Dr. White, of Toronto, Secretary; Dr. Graham, of Toronto, Treasurer.

Dr. Lucian Howe, of Buffalo, was present as a delegate from the New York State Medical Society; Drs. Jenks and Brodie, of Detroit, Roswell Park, of Buffalo, and Stewart, of Montreal, as invited guests.

A telegram conveying fraternal greetings was received from the Wisconsin State Medical Society, in session in Milwaukee, and its congratulations were replied to and reciprocated.

The President's address referred to

THE SIX DISEASES MOST FATAL AT THE TIME OF SYDENHAM.

As stated by that talented physician these were plague, ague, dysentery, scurvy, puerperal diseases, and small-pox. The lessened mortality from these was due to a better understanding of their causes, their prevention, and their treatment. He next took up the study of fevers, and traced the changes in the opinions held regarding their pathology. Currie and his use of cold water was spoken of, and in particular attention was drawn to the fact that he used the thermometer under the tongue, or in the axilla, to estimate the reduction of temperature. He antedated Wunderlich's discovery by half a century or more, and by a still longer time the adoption of this help to diagnosis by the profession at large. In conclusion, the President made a forecast of the progress that will take place in medicine in the next hundred years.

A report, presented by

THE COMMITTEE ON MEDICAL ETHICS,

dealing with the question of consultation with homœopaths, was laid upon the table till next year.

As proposed last year, a discussion on diphtheria was next in order, and was opened by Dr. Tyce, of Chatham. His paper was a masterly exposition of the subject by one whose experience upon it has been exceptionally

large. Fifteen members took part in the discussion, which at times became quite animated.

Dr. Bray, of Chatham, followed with a paper on

CÆSAREAN SECTION.

The history of a recent case was given, and was interesting as being perhaps the only one on record where a woman who has given birth naturally to several children has afterward required so serious an operation to accomplish her delivery. A pelvic fracture, with great displacement of the bones, created the difficulty in this instance.

Dr. Jenks, who had performed the operation, spoke upon the paper. His statement, that craniotomy should largely give place to the Cæsarean section, was dissented from by several gentlemen who had succeeded repeatedly with it after failure by all other means. They did not believe the results would have been so favorable had abdominal section been made. In closing the discussion Dr. Jenks ably maintained his position, and declared that in cases of marked pelvic contraction Tait's operation, or *castration*, was to be preferred to the repeated performance of craniotomy.

Dr. Fraser, of Sarnia, in a paper on

CONTINUED FEVERS,

said that, in malarial districts, typhoid fever developed in an irregular and uncertain manner in the majority of cases. Though its course is modified by malaria, the term "typho-malarial fever" is inaccurate and misleading. In the discussion upon this paper wide differences of opinion were brought out as to whether or not there existed a distinct fever between typhoid and malaria. The general consensus of opinion was against such a conclusion.

Dr. Powell, of Edgar, Chairman of the Committee on Surgery, opened the discussion on the use of

PLASTER SPLINTS AND PLASTER BANDAGES IN THE TREATMENT OF FRACTURES.

Materials and methods were spoken of, also the stage at which such plastic dressings should be used, and the fractures for which they formed the best retention apparatus. They were advised for the lower jaw, arm, elbow, patella, and leg, and condemned for the forearm and thigh. Hinged splints, or those on the model of the "plaster posterior splint," should be used in the early stages, and spiral bandages for the later ones. Finally, the risks and the advantages of these dressings received attention, and samples to illustrate their various applications were shown. The paper was discussed by Drs. Roswell Park, of Buffalo; Groves, of Fergus; Bray, of Chatham, and others.

Dr. Howe, of Buffalo, read a paper on

THE BLINDNESS OF PREGNANCY,

in which he endeavored to prove: 1, That pregnant women are liable to an impairment of vision which, though sometimes stationary, may become permanent; 2, that this is due to an inflammation of the retina, caused by albuminuria; 3, that the danger to vision alone, or to life and vision, is sufficient, in certain cases, to warrant premature delivery, or even abortion. Proof was given that the danger to vision was an index of the danger to life, and the cases requiring active interference were differentiated from those which might be treated expectantly. The appearance presented in these cases was illustrated by pictures thrown upon a screen.

A cordial vote of thanks was passed to Dr. Howe for his interesting and suggestive exposition of the subject.

Dr. Groves, of Fergus, read a paper on

RENAL CALCULI.

He stated that very many patients suffering from the presence of these concretions fell under the care of those who, like himself, practised along the banks of the Grand River. As regards treatment during attacks of renal colic he attaches the first importance to the inhalation of chloroform. Hot baths and mild anodynes he had found entirely inefficient.

The work of the first day was closed by a paper on "Placenta Prævia," by Dr. Edwards, of London.

On the second day Dr. Temple, of Toronto, Chairman of the Committee on Obstetrics, opened a discussion upon "Intra-uterine Medication." His paper was exceedingly practical, and presented all the more recent and reliable advances in this line of practice. It was commented upon by Drs. Holmes, Roseburgh, and Powell.

Two brothers, suffering from pseudo-hypertrophic muscular paralysis, were shown by Dr. Edwards, of London, and their disease was discussed by Dr. Stewart, of Montreal. He stated that galvanism applied to the spine was considered to have cured several cases seen at an early stage.

Dr. Roswell Park, of Buffalo, followed with a volunteer paper on the

SURGICAL SEQUELÆ OF FEVERS.

Many cases illustrating the various lesions coming under this head were placed for the first time on record. An important paper, written by Dr. Kerr, of Philadelphia, was referred to, and much additional light thrown on a subject worthy of close observation.

Dr. Aiken, of Toronto, was in accord with the reader, and added to what he had advanced the conclusions derived from cases he had been called upon to treat.

At this stage it was found necessary to divide into sections in order to get the papers all before the Association. Dr. Graham, of Toronto, presided over that on Medicine, and Dr. Aiken, of the same city, over that on Surgery and Obstetrics.

Dr. Henderson, of Kingston, led off in the first section with a paper upon

PULMONARY CAVITIES.

No abstract can do justice to this careful study of a diseased condition second in importance to no other.

Drs. McDonald and Graham, of Toronto, took part in the discussion it evoked, and the general opinion expressed was in the direction of sustaining the contentions of Koch regarding the connection between bacilli and phthisis.

Dr. Duncan, of Thamesville, on "Warburg's Tincture," Dr. Owens, of Arkona, on

ON TRIFACIAL NEURALGIA,

and Dr. Arnott, of London, on "Diet in Disease," closed the work in this section by papers worthy of more attention than it is possible to give them here.

A paper was also read on "Mitral Stenosis" during the afternoon by the Chairman, Dr. J. E. Graham, of Toronto.

In the Surgical and Obstetrical Section, papers were presented on "Hemorrhage after Abortion," by Dr. Murry, of Thorndale, and on "The Treatment of Abortion," by Dr. Adam Wright, of Toronto; one of characteristic vigor and originality by Dr. Harrison, of Selkirk, and one upon "Intestinal Obstruction" by Dr. Atherton, of Toronto.

Dr. Youmans, of Mount Forrest, was down for a paper on "Compound Fracture of the Patella," but unfortunately had to leave by an early train. Finally, the discussion on "Cocaine Hydrochlorate" was opened by Dr. Reeves, of Toronto, and taken part in by Drs. Howe, of Buffalo, and Palmer, of Toronto. The

OFFICERS ELECTED

for next year, when the Association will meet in Toronto, were: Dr. Tyce, President; Drs. Arnott, Temple, Hillary, and Henderson, Vice-Presidents; Dr. White, Secretary; Dr. Graham, Treasurer; Drs. Wright, Campbell, Aylesworth, and Mitchell, Corresponding Secretaries.

MEDICAL SOCIETY OF THE STATE OF OHIO.

Fortieth Annual Session, held at Dayton, O., June 3, 4, and 5, 1885.

(By Telegraph to THE MEDICAL RECORD.)

SECOND DAY—THURSDAY, JUNE 4TH—MORNING SESSION.

(Continued from page 636.)

An amendment to the Constitution, admitting applicants for membership from counties where there was no Medical Society, was rejected. The argument in favor of this amendment was that there were eighteen counties in the State which contained no Medical Societies, and hence the applicant could not conveniently, as required by the Constitution, belong to a local Society.

On motion of Dr. Franklin, $500 was appropriated to carry through the bill for a State

BOARD OF MEDICAL EXAMINERS,

defeated last year by but three votes.

DISEASES OF THE SPINAL CORD.

Dr. Philip Zenner, of Cincinnati, next read a paper on the above subject.

The author's reasons for presenting this subject were comparative frequency and difficulty of diagnosis. Errors of diagnosis, however, were often due more to a want of knowledge of the facts necessary than from obscure symptoms.

To prove this the author cited a number of cases from his case-book, in which erroneous diagnoses had been made by men of ability.

Case I.—Treated for rheumatic pains. History of severe and frequent lancinating pains, anomalous sensations, numbness and formication in the lower extremities, also constriction about the waist, some impairment of the sensation in the lower extremity, and a degree of insecurity on the feet with the eyes closed and absence of the patellar tendon reflex, and some impairment of the gait, worse at night, were found. The symptoms in this case were so pronounced that an error in diagnosis ought not to have been made. Essayist wished to lay special stress upon following symptoms, which enable us even at an early period to make a positive diagnosis. These are the characteristic lightning pains, the absence of the patellar tendon reflex, and the presence of certain ocular symptoms. The latter are transitory paralysis of some of the external muscles of the eyes, causing double vision, the so-called Argyle-Robertson phenomenon, the pupil being small, not responding to light, but contracting during the act of accommodation, and, more rarely, atrophy of the optic nerves. One other, the Brach-Romberg symptom, inability to stand with the closed eyes.

Case II.—Had experienced slight difficulty in walking or six years past, also had bladder symptoms, that is, inability to hold water for a length of time. Locomotor ataxia had been diagnosed, but the conditions present were quite different from those of that disease. The gait was feeble, not ataxic. Often a feeling of stiffness was felt in the limbs. The patellar tendon reflexes were exaggerated and the foot clonus could be elicited. The three important symptoms were not present. In locomotor ataxia the posterior columns of the cord are affected; in this patient the antero-lateral, and the disease—lateral sclerosis. It may seem that the location of the disease in the lateral or posterior columns is too nice a diagnosis to be practicable, but it is not so; not only is there a marked difference in the subjective symptoms, but the prognosis of the latter is decidedly better.

Case III.—She had noticed some weakness in her lower extremities four years previous to his seeing her. She could not lift her feet in walking as well as formerly, nor could she arise from the sitting to the standing position easily. When seen by the essayist, the deltoids, the biceps, and the quadriceps femoris of both sides, and many muscles of the back were completely paralyzed. On arising to the erect posture she succeeded in extending the knees by pressing with the hands on the thighs and raised the trunk by means of a chair or external support. A remarkable curve of the spine was produced by these efforts. It seemed as though there were no unyielding parts about the spinal column. From this one of the physicians who saw her supposed that she had disease of the vertebra. In addition to the paralysis of the muscles there was atrophy and loss of electrical contractility in the same. This latter is a point of much importance. These, together with the history of gradually extending paralysis, are quite enough to diagnose progressive muscular atrophy, though in this case the development was an unusual one.

Case IV.—Mrs. L——, aged fifty-two, had been operated upon for carcinoma of the mammary gland. Eight months later severe pain like that of intercostal neuralgia occurred. Subsequently severe pain in the lower extremities, hyperæstheria of the surface, and paraplegia and some atrophy of the muscle of the legs. Myelitis had been diagnosed. Author emphasized the gradual access of the symptoms, the severity of the pain—seldom if ever found in ordinary myelitis—and the history of previous malignant disease. Upon these facts he made the positive diagnosis of malignant disease within the vertebral canal, and prognosis of a fatal issue within one year. The subsequent course of the disease strengthened the diagnosis, and death occurred in nine months. The autopsy showed numerous carcinomatous nodules in the vertebræ and the cord. The earlier manifestations were quite sufficient to make a correct diagnosis. Paraplegia, with pain so severe that it is designated by paraplegia dolorosis, is rarely if ever found, excepting with malignant disease. A previous history of this disease should leave no doubt of a diagnosis.

A few cases of neurasthenia would contrast well the functional and organic diseases of the cord, but would occupy too much time. The essential thing is to exclude organic disease. If a patient comes to us with a history of pains, weakness, or anomalous sensations pointing to the cord, we should examine as to the presence of ocular symptoms, as to the condition of the cutaneous sensibility, as to the tendon reflexes and the action of the bladder and rectum, and the kind of gait, to discern the presence of locomotor ataxia. We should then examine further to see whether any motor paralysis, with increased tendon reflexes and rigidity of muscles point to diseases of the motor columns of the cord; or paralysis and atrophy of the muscles, with altered electrical reaction, point to affection of the gray matter. If all these symptoms can be excluded, we are probably in the presence of only a functional disease, which, with time and proper treatment, can be entirely removed, and whose positive diagnosis will bring immediate mental relief to an anxious, perhaps despondent, sufferer.

Dr. P. S. Conner, of Cincinnati, read a paper on the subject of

VESICAL EXPLORATIONS.

He referred to the great difficulty of diagnosis in many cases, and thought endoscopic examinations were not satisfactory. When the usual methods fail, we should resort to digital explorations. He lauded the perineal section as being comparatively void of danger, and affording immense value in diagnosis. Had operated over one hundred times. In no case was death due to the section. Was not in favor of the suprapubic operation of the French surgeons. In very young children lateral, rather than median, urethrotomy should be made. Though of less value in fat subjects, perineal section still afforded much advantage with them.

Discussed by Drs. Ransohoff, Holland, and Thorn.

Dr. R. Harvey Reed, of Mansfield, read a paper on

VITILIGO,

which Duhring describes as an acquired disease, consisting of one or more sharply defined, rounded, or irregu-

gularly shaped, variously sized, and distributed smooth whitish spots. Dr. McCall Anderson met only four cases in an analysis of one thousand cases. He then discussed the points bearing on the differential diagnosis from morphæa, chloasma, tinea versicolor, and impetigo, and reported four cases. Treatment with him has been very unsatisfactory. Authors generally agree that this is of nervous origin. The essayist will believe this to be a purely nervous disease under protest.

SECOND DAY—THURSDAY, JUNE 4TH—AFTERNOON SESSION.

The President, DR. J. C. REEVE, of Dayton, delivered the usual address. His subject was:

SYSTEMS IN MEDICINE.

He spoke of the evolution of medicine. Though even yet very imperfect, medicine, both in the present and past, compares favorably with law or theology. It has always taken on the character of the age. For a long time it was bound to philosophy. Medicine to day takes on the spirit of the age—active, practical, advancing. He would have been a bold man who, at our last annual meeting, would have said, "Before we meet again ether and chloroform will be discarded as anæsthetics for eye operations." He referred to the absence of any theory of disease. Theories and hypotheses are the servants of the human mind; systems are its master. To some of these systems he wished to direct attention. All systems owe their origin to the imperfections of medicine at the time of their origin. They accomplish a little good, the greater part passes into oblivion. He then went more particularly into a consideration of homœopathy, bringing up the absurdities of the sect. Homœopathy had existed for three-quarters of a century. In that time the regular profession had given to the world the stethoscope, ophthalmoscope, laryngoscope, ether, chloroform, cocaine, chloral, etc., etc. What has homœopathy given? Nothing.

The following officers were elected: Dr. W. Morrow Beach, of London, President; Dr. H. C. Gill, of Cleveland, First Vice-President; Dr. H. R. Kelly, of Gallion, Second Vice-President; Dr. Thomas Markbreit, of Akron, Third Vice-President; Dr. J. D. Robinson, of Wooster, Fourth Vice-President; Dr. T. W. Jones, of Columbus, Treasurer and Librarian; Dr. G. A. Collamore, of Toledo, Secretary; Dr. E. C. Bush, of Zanesville, Assistant Secretary.

The place of meeting will be Akron, the first Wednesday, Thursday, and Friday in June, 1886.

DR. ISAAC N. HIMES, of Cleveland, read a paper on the subject of

REMARKS AND CASES CONNECTED WITH MEDICAL EXAMINATIONS FOR LIFE INSURANCE.

The Doctor wished to notice some subjects in his paper, not chosen because of a special importance, but such as have an occasional or recurring interest to those who, as an accompaniment of their medical and surgical practice, have to do with examinations for life insurance. He treated of the influence of life insurance upon the hygiene of cities, questions of doubt concerning the respiratory organs, phenomena connected with the circulation of the blood, the place where the examination was made, rejection of applicants, albumen and sugar in the urine.

DR. GEORGE W. RYAN, of Cincinnati, read a paper on

THE TREATMENT OF SPINAL IRRITATION.

The essayist considered this condition more particularly in its relationship to joint trouble coming especially under the care of the orthopædic surgeon. Cases which have worn apparatus for months have often been relieved by treatment addressed to the cause of the disease. He advised examination of spine in every case of doubtful joint trouble. He reported two cases in which treatment by the Paquelin cautery, faradism, and spinal support were used advantageously. Had seen excellent results from large fly-blisters. Thought the value of spinal support had been underestimated.

DR. WILLIAM T. CORLETT, M.D., F.R.C.P., of London, read on the subject

DISEASES OF THE SKIN OF A REFLEX NERVOUS CAUSATION.

He spoke concerning the senso-neuroses and the tropho-neuroses, reporting a number of cases. The most marked tropho-neuroses coming under his observation have closely resembled eczema. Senso-neuroses are, *cæteris paribus*, more frequently associated with conditions of a mild nature, whereas tropho-neuroses, *cæteris paribus*, more frequently accompany pathological conditions of a graver import.

The papers of Drs. Ryan, Zenner, and Corlett were discussed together, Drs. Reed, Beach, Gill, Herrick, and Brinkerhoff taking part.

THIRD DAY—FRIDAY, JUNE 5TH—MORNING SESSION.

DR. RUFUS B. HALL, of Chillicothe, read a paper on the subject of

ABDOMINAL SECTIONS,

treating of this interesting subject in a masterly and instructive manner.

DR. H. G. LANDIS, of Columbus, read a paper on

OCCIPITO-POSTERIOR POSITIONS.

The chief points considered were the diagnosis, notably of anterior rotation. Caution was given about the use of the forceps. The points were illustrated with numerous cases.

DR. H. J. HERRICK, of Cleveland, read a paper on

DIETETICS OF TYPHOID FEVER.

DR. JOSEPH RANSOHOFF, of Cincinnati, reported a case and exhibited a specimen of

URETHRAL CALCULUS.

DR. W. M. BEACH, the newly elected President, made a brief speech, and the retiring President, DR. J. C. REEVE, delivered his valedictory.

Adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 4, 1885.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. RICHARD H. DERBY read a paper (see p. 650) entitled

CONTAGIOUS OPHTHALMIA IN SOME OF THE ORPHAN ASYLUMS AND RESIDENTIAL SCHOOLS OF NEW YORK CITY.

The discussion was opened by DR. H. KNAPP, who said he had listened with interest to the statements of the speaker, and could in no way underrate them, but he did not feel certain that either the spread or the outbreak of the disease was at all preventable; for, as long as there were so many uncared-for children in large cities, it seemed almost impossible to prevent the disease entirely. The idea that all these institutions should have a certain amount of supervision with reference to the reception of inmates, he thought, was correct, and should be enforced. If all of the institutions had as one of their regulations to report once a month, for example, the condition of the eyes of the inmates, he thought that, to a very great extent, outbreaks of the disease could be prevented. If all the institutions were closed and the children farmed out, the spread of the disease could be more definitely regulated. Certainly no more philanthropic undertaking could be engaged in than that involved in the subject of the paper of the evening.

Dr. Roosa said he had this afternoon examined two hundred and forty-two children at the request of the attending physician of one of our public institutions, and found sixty-seven affected with conjunctivitis, generally of a mild type and probably curable, but these sixty-seven required treatment, and they were under as good care as could be had without isolation. If the Board of Health possessed any power to correct such matters, the question was one which really belonged to that board, and the authorities of the institutions were not entirely responsible for this state of affairs. He believed, however, that it was better to allow the children to remain in the institutions with good food and air, than to send them back to their homes in tenement-houses. The good work inaugurated in this field had already brought forth considerable fruit, as the disease appeared to be chiefly a local affection, and the old notion that struma and this class of troubles were intimately related did not seem to hold good, at least in New York. Dr. Roosa thought the remedy for the correction of the evil was at hand, and it was that the tax-payers of this city should pay for a hospital in which such children could be treated and retained until they had recovered, and the reduction of the pauper class by curing the eyes of these children at a time when they are curable was a sufficiently important undertaking to be worthy of the attention of political philanthropists. There should be begun at once a hospital of this character, and the Board of Health should insist upon the erection of such an institution, as it seemed to him the question came to that board, which had charge of the sanitary condition of this city.

Dr. Oatman, of Nyack, by invitation, referred to an institution under his charge in which there were one hundred children, all healthy when admitted except two, whom he endeavored to have isolated. He was unable, however, to accomplish this, and finally a mild catarrhal affection of the eyes developed, and it went on until this spring, when he finally succeeded in having the affected children quarantined, and there were forty-four who had catarrhal disease of the eye, probably contagious. Of the forty-four, seven had acute granular trachoma and one purulent ophthalmia. All of these children were quarantined and given abundance of food, and the benefit of the plan manifested itself promptly.

Dr. C. R. Agnew said that his interest in this subject began thirty years ago, in connection with the results of famine in Ireland at that time, and from whose stock of granular lids, one of the results of overcrowding and want, we had been receiving contributions ever since. Dr. Agnew referred to one large school where the children affected were taken out-of-doors and put into tents, and the supply of good milk increased many-fold, with the result of producing a marked improvement in their general condition and also in the condition of their eyes. The inducement on the part of institutions, which received a certain amount *per capita* for board and care, to admit as many as possible, was certainly to be taken into account. He thought it was insufficient to have boards of examination from the non-professional alone, however intelligent in ordinary business transactions they might be, for it was not even every general practitioner whose opinion as to the condition of the eyes could be safely trusted. There should be some expert examination. He should dislike to go to the State and ask for legislation, and had thought that agitation could do very much toward correcting the evil, but after having given thought to the matter for several years, he had been driven to the belief that we need some legislation, some law by which all these questions, which have to be settled by boards of managers or by social position, could be definitely arranged. A vast number of children having chronic conjunctivitis never recover, and helped to make up that immense body of drifting, despairing characters which invade our country. There was plenty of indigenous pauperism which grew up under our very eyes, and which would continue to exist, unless we set about it and combined all possible agencies to prevent its further development.

Mr. T. Elbridge Gerry, President of the Society for the Prevention of Cruelty to Children, on invitation, participated in the discussion, and said that he agreed with Dr. Agnew on the point of providing for oversight of all these institutions by competent and recognized medical authority; that the Society over which he presided would be glad to co-operate in the adoption of any measures which would be for the best interests of the children. He spoke in favor of sending all patients requiring treatment to pay hospitals already in existence, rather than building new hospitals for this special purpose. Mr. Gerry then spoke at considerable length with reference to the legal steps necessary for the commitment of children, and pointed out some of the obstacles to such an assignment of children as might seem necessary from a medical standpoint.

Dr. J. J. Milhau, of the State Board of Charities, spoke concerning the law which regulated the action of that board, and corrected a slight error in the statements made by Mr. Gerry concerning the exact point at which the difficulty existed with reference to the proper assignment of children to our public institutions.

The President remarked that all of these institutions were meant to do good, and it was expected of them that they would accomplish their work; but all of them did a great deal of harm, for, so long as large numbers of children were collected, just so long would the possibility of danger be maintained. Ophthalmia was a contagious disease, and when it entered, it destroyed both the eyes and the general health, and all care in admitting to public institutions children afflicted with this disease would be useless to a considerable extent. Public institutions, as a rule, were overcrowded, and the children would die there the same as elsewhere, and he believed that they were much better off in their homes, even in tenement houses, than they were in the great aggregations under public charge. A disease which would be very mild in private dwellings would become dangerous in public institutions, and if it was proposed to simply add an eye-hospital to existing institutions, it would be one where treatment would be found all that could be desired, but where an accumulation of cases would take place, and a mild form of ophthalmia would become a serious one, and probably not much would be effected by such a multiplication of public institutions.

Before final steps were taken in the matter, the question would arise whether permission should be given to erect such institutions at all, and whether more harm than good would not arise from their erection. Dr. Jacobi thought that if the same amount of money expended in the erection of such institutions were expended in farming out children, they would be very much better off than they could possibly be in such institutions, however well regulated, and surely we should have more children and less blind ones.

Dr. W. F. Mittendorf thought that in discussing this subject it was extremely difficult to make the people understand two points: First, the great danger to eyesight in consequence of contagious ophthalmia, and, second, the length of time required to cure the disease. An institution once having become infected, it was almost impossible to eradicate the poison. According to his experience in some of the large institutions in the city, he coincided with the views of the President, that crowding children into large buildings would also be a source of very great danger. In the New York Infant Asylum and the branch of the Nurse's and Child's Hospital, the children were kept in cottages, and but very little trouble with their eyes had been seen. He therefore thought that, if such institutions must be erected, the cottage plan was probably the best, as the best treatment was strict isolation in the institutions where the children may be when attacked with the disease. There should be as few children as possible in one building.

Dr. Agnew introduced the following resolutions:

First.—It is necessary and expedient that steps be taken to prevent the occurrence of communicable eye-disease in the schools and the asylums of New York and vicinity.

Second.—That the New York Academy of Medicine take the matter of the paper of the evening into its immediate consideration, and that the competent co-operation of the writer of the paper, the Society for the Prevention of Cruelty to Children, the State Board of Charities, the State Charities Aid Association, and others, be invoked for the purpose of lessening the prevalence of communicable eye-disease.

Dr. Roosa thought that, taking things as they are, and not as they will be in Utopia, and from the experience already obtained in those schools where epidemics have been stamped out, it was not quite right to draw the picture so strong regarding the incurable nature of the disease as had been done; for these children had been cured by the dozens and hundreds. He cheerfully seconded the resolutions offered by Dr. Agnew, but he would not second a resolution which said that all that was necessary was simply to get a law to prevent children with ophthalmia from being admitted to public institutions.

The resolutions were unanimously adopted.

The Chairman of the Committee of Ways and Means, Dr. Gouverneur M. Smith, made an additional report, containing a report of the Treasurer of the Committee, Dr. Willard Parker, concerning the amount which had been paid toward the liquidation of the mortgage on the Academy building.

Dr. Agnew offered a resolution providing for the transfer by the Treasurer of the Academy to the Treasurer of the Board of Trustees of such surplus funds as could be used for the further liquidation of the mortgage.

The Academy then adjourned.

Correspondence.

OUR VIENNA LETTER.

(From our Special Correspondent.)

THE VIENNA OBSTETRICAL SERVICE.

Vienna, April 23, 1885.

In the Vienna Obstetrical Hospital are confined every year about nine thousand patients. The remarkably low mortality and freedom from puerperal diseases in this hospital have made it well known all over Europe, and a description of the rules and methods in use in the obstetrical wards ought to be of some interest to the general practitioner. The immunity from childbed disease cannot be due to climatic influences, because outside of the hospital in Vienna, and in the surrounding country, puerperal fever is of frequent occurrence, and the mortality is high. To the treatment in the hospital itself must the good results be attributed.

The patients are not usually admitted to the hospital till a week before confinement. They come principally from the eastern and northern parts of Austria, and the great majority are stout hearty country women in robust health and very favorable patients. This vast material is divided up into three equal divisions under the charge of Professors Carl Braun, Gustave Braun, and Spaeth. The methods in use in the different divisions do not differ essentially. Those in the service of Professor Carl Braun will be described. The building in which the patients are delivered and kept during convalescence has been in use for this purpose for the last hundred years, and is part of the general hospital building in which the surgical and medical cases of the city are kept. The confinement-room is in almost continuous use. It is about sixty by twenty feet, and contains fourteen to sixteen beds (slightly larger than the larger pavilions of the New York Maternity Hospital, which contain only nine beds). Opening into this room is a smaller one nearly sixteen feet square, into which patients with a rise of temperature during labor or other marked complications are transferred. Both rooms are about twelve to fourteen feet from floor to ceiling and have small windows in the upper part of their walls. No especial antiseptic precautions are used in disinfecting these rooms, except that they are thoroughly cleaned with soap and water and opened to the air a few hours every third day. The walls are whitewashed twice a year. Any student may deliver normal cases in the ward. He may examine externally all cases in the ward, but internally only the case he intends to deliver. As soon as this case is delivered, if the temperature is under 37.5° C., he may immediately take another case. The antiseptic precautions taken before confining cases are, washing the hands thoroughly with soap and water with a nail-brush, dipping them in weak solution of permanganate of potash and then in a two per cent. carbolic solution. A rule, to which not the slightest attention is paid, prohibits practitioners from coming directly from the dead-house, or from operations on the cadaver, and examining cases per vaginam or delivering. I have several times seen the obstetrical assistants make vaginal examinations and even operate within a few minutes after operating on a cadaver, and with only the antiseptic precautions mentioned, with, as far as I could ascertain, no bad result.

The entire absence of medicine to hasten the labor when too slow, or relieve severe pains, or to induce them when wanting or feeble, is noticeable. Avoidance of any kind of interference in labor is carried to the greatest extreme. Even for forceps operation or a version, unless extremely difficult, no anæsthetic is administered. Great care is taken also to prevent the least injury to the os uteri. The utmost respect is paid during labor to this part. It must dilate normally and in its own time. Artificial dilatation is not permitted even with the finger, and all mechanical appliances for dilatation are "inventions of the devil." The placenta is usually expelled by Crède's method. After its expulsion, in all cases, an injection deep into the vagina is given of 1 to 3,000 bichloride of mercury solution, and of late a weak solution of thymol has been substituted for the bichloride with good results. After the injection, if slight lacerations are found on the vaginal mucous surface, these are powdered with iodoform, and, with no further dressing, the patient is transferred to the convalescence-room. All the normal deliveries are made in the large room; and it sometimes happens that every bed in the room will be occupied by a patient in labor. Patients are always confined on their back except in cases of primiparæ, where the Vienna method of supporting the perineum is used. As soon as the child's head begins to stretch the perineum, the patient is laid on her left side, buttocks supported on a pillow brought well over onto the edge of the bed. The legs are then separated by an assistant on the other side of the bed. The operator, standing on the right, passes the left hand over the patient's abdomen and between the legs upon the child's head, the thumb and fingers separating and protecting the labiæ. The right hand, covered by a towel, is placed flat over the anus and perineum, and during a pain forces the head firmly forward and upward against the symphysis. The patient at the same time is instructed to cry out. Meanwhile the perineum is gently distended and moulded, and finally the head "shelled" out between the pains, the peculiar grasp of the head giving perfect control against too forcible distention of the perineum by a sudden pain. The midwives here have become so adept in this method that a rupture of the perineum in one case in a hundred primiparæ is a rarity.

When ruptures occur after natural or instrumental delivery, great care is taken in the after-treatment. After thorough irrigation the lacerations are immediately sewn up, always with silk sutures; catgut or silver wire is not employed on the service. Lacerations of the os are also sewn up immediately after delivery. In all forceps cases,

after the expulsion of the placenta, the patient is examined for tears in the os. If they are found, the patient is placed upon a table in Sims' position, usually without an anæsthetic, and the torn lips of the os are brought down and sewn together. If large lacerations are present in the vaginal mucous surface, stitches are also put in these. A uterine injection of 1 to 3,000 bichloride or thymol is then given, after which two to four pencils of iodoform of 0.5 each are pushed into the uterus, two or three vaginal pencils of 3 each of iodoform inserted in the vagina, the os uteri, vaginal surface, and sewn perineum are plentifully sprinkled with iodoform powder, a wad of absorbent cotton covered with iodoform is placed over the vulva, and the patient removed. This dressing is not renewed, the only treatment of normal cases being weak bichloride vaginal injections once a day for the first two or three days. Simple lacerations of the perineum are sewn up in the same way, the stitches are removed from os and perineum on the sixth day, and in almost every case primary union of all the lacerations has taken place, and a perfectly normal convalescence ends on the tenth to twelfth day, when the patients are discharged. Professor Carl Braun has also a very large gynecological service, with the same staff of assistants as in the obstetrical wards. Severe operations are very frequent in this division, and I have seen the nurses on duty in the confinement-room at the same time attend operations in the gynecological clinic, the assistants naturally being obliged to attend both divisions. The two services are in the same building, and often the rooms adjoin.

In spite of these apparent disadvantages the mortality from all causes, in the maternity service, was less than one-half of one per cent. In seven hundred cases delivered in October, November, and December, 1884, there were only three deaths from all causes; the only septic case was one of Cæsarian section, the particulars of which I related in a former letter.

The mortality among the children is a very high one; the last year it was in the neighborhood of fifteen per cent. Into the problem of how to reduce this mortality enter social and political factors which cannot be controlled so as to give a satisfactory solution.

ROLLER-SKATING FOR GIRLS.

To the Editor of The Medical Record.

Sir: I am very much interested in this subject of "roller-skating" for girls; especially so because I have from thirty to forty girls under my care for physical training and treatment. Theoretically, I believed it was going to be a good thing, but my experience is forcing me to the conclusion that no good, moral, mental, or physical, comes from this source. With the utmost care as to time and amount, I find it unsatisfactory. It seems to bring out any latent predisposition to disease. I have been compelled to forbid those who had the slightest tendency to kidney or heart trouble, in fact, any organic trouble, indulging in the sport. In one case only, of enlarged liver, subject to acute attacks of congestion, etc., I have seen no bad effect. A case of anæmia, the most intractable one I ever had to deal with, I am sure was caused by skating excessively. The disease had so far yielded that I, in an unguarded moment, said "Yes" to a plaintive "Just one hour, please?" and the result was severe vomiting of the next meal. She has been able to take no food without great uneasiness since, and I see I'll have much of the old ground to go over. Those who have skated very much before coming here have leucorrhœa, and confess it is aggravated by the limited amount of exercise I have allowed. I would like to know as to the observations of others in the case of *limited* indulgence. There is no question now about excessive skating, but can we let young girls take even a limited amount without injury? Very respectfully,

Julia Townsend Hill, M.D.

THE INTERNATIONAL CONGRESS AND THE NEW CODE.

To the Editor of The Medical Record.

Sir: Permit me to say in reference to the recently published correspondence between Dr. Jacobi and myself, that the letters were of a personal nature and were injected into the journals without any authorization on my part, or cause on the part of Dr. Jacobi. I have nothing to retract from the statements which I made at the meeting of the American Medical Association in New Orleans. They are absolutely true and can be substantiated by better evidence than the words of Dr. Jacobi. When the time that I deem proper shall arrive, I will demonstrate the non-truthfulness and real inwardness of Dr. Jacobi's assertions in such a way that not one of your impartial readers will have any doubt of the justice or of the propriety of my remarks at New Orleans.

I have no desire to bandy words with Dr. Jacobi on questions of veracity. My status in my own community is certainly as good as that of Dr. Jacobi in New York. I have never referred to or mentioned him in public in connection with the American Medical Association or the International Congress. At present he is simply his own accuser in the matter, but it is well said that "The wicked fleeth when no man pursueth."

Yours respectfully,

John V. Shoemaker, M.D.

Philadelphia, June 1, 1885.

CONCERNING DIGITAL EXPLORATION OF THE BLADDER.

To the Editor of The Medical Record.

Dear Sir: It seems almost amusing to see the alacrity displayed by some of our foreign cousins in appropriating American ideas without giving their authors the slightest credit, and then proceeding to make personal capital out of them.

One of the most glaring of these plagiarisms is the recent attempt on the part of Sir Henry Thompson to claim originality for a "new" method of diagnosis in obscure diseases of the bladder by means of digital exploration through a perineal opening.

In his lectures on "Surgery of the Urinary Organs," p. 29, published in London, October, 1884, this author, in speaking on the subject, says: "The object with which I have recently proposed to operate is a *new one*, inasmuch as it is solely the exploration of every part of the bladder with the end of the finger, in order to diagnose its condition. . . . I made the first published account, not in this country but in *La Semaine Médicale*, Paris, June 18, 1882."

It seems strange to Americans who have enjoyed the clinics of the late Professors S. D. Gross and James R. Wood, to hear this point set forth, at this day, as a "*new*" one, and in *The Annals of Anatomy and Surgery*, July, 1882, Dr. Stein, in his "Study of Rupture of the Bladder," referring to diagnosis, says: "Last, but not least, comes digital exploration of the interior of the bladder. In the female this is accomplished readily enough through the short urethra. In the male it is effected through a small median perineal incision made on a staff in front of the prostate. The practicability of this procedure has been verified, its execution is both simple and safe, and as a means of diagnosis it is, without doubt, the most efficient and reliable at our command."

It will be observed that Dr. Stein makes no claim for originality; but had Sir Henry Thompson made a little more careful study of this author's works, and credited him with what he justly deserves, he would have escaped errors both of omission and commission.

L. L. Seaman, M.D.

Charity Hospital, N. Y., June 4, 1885.

AN EFFORT TO MEET THE ABUSE OF MEDICAL CHARITIES WITH THE AID OF THE CHARITY ORGANIZATION SOCIETY.

To the Editor of The Medical Record.

Sir: That our dispensaries and other medical charitable institutions are frequented by numerous patients well able to pay is a well-known fact. How to prevent this abuse has proved a difficult and troublesome question. Since the opening of the new building of the German Dispensary in 137 Second Avenue (with over thirty thousand patients in 1884), there was an exceptionally large run of such unwelcome patients, so that the medical staff had earnestly to think of some measure of relief.

To get an idea to what extent people able to pay were seeking aid in the dispensary, three members of the medical staff, who had been appointed a committee for this purpose, examined, during the month of December, all persons applying for treatment, as to their residence, family relations, income or means of support, etc.

From the information thus received the committee saw good reason to turn away eight per cent. of all the applicants as being fully able to pay for doctor and medicine. This class comprised those who never intended to ask for gratuitous advice, but expected to pay at the dispensary, etc., or those who were under some misapprehension—for instance, that the doctors were well paid for their work, etc.—or small storekeepers and mechanics, who, by former experience, had been taught how easy it is to get medical advice, and even medicine, for nothing. Still they are not the most dangerous class to deal with, but it seemed in the cases of about nine per cent. of the applicants doubtful if they were entitled to admission, because their answers were either unsatisfactory or not to be trusted.

Here arose the real difficulty, how to find out the truth about their statements. The Charity Organization Society of the City of New York was thought of, and on being approached by our committee on this subject, the former declared its willingness to investigate all our doubtful cases and report about them as quickly as possible if the German Dispensary became a member of their Society.

On presentation of this matter by the medical staff, the trustees of the German Hospital and Dispensary agreed to the conditions of the Charity Organization Society—the payment of $100 for six months as a trial.

So from January 1st, all cases reported as doubtful regarding inability to pay for doctor and medicine by the physicians and surgeons in attendance were sent to the different agencies of the Charity Society or to their central office. The answers came in very promptly, and after three months' work we take leave to present to the medical profession the results of this investigation. During the first three months of the current year we sent in 192 names for investigation, they were reported upon as follows: Fully able to pay, 64; not able to pay, 65; false addresses, 63.

So many false addresses seem to be given probably intentionally, as many of the numbers given represent empty lots, stables, factories, etc., and urge to the belief that of those who have given wrong numbers a good percentage was also fully able to pay. To sum up the result of the investigation by the Charity Society of all doubtful cases, it is shown plainly that about fifty per cent. of all those investigated were *fully* able to pay.

Executive Committee of the
German Dispensary.

[We are glad to note the continuance, by the managers of this institution, of the good work we alluded to in our last week's issue. The above facts suggest volumes in regard to the work of charity and the discrimination between worthy and unworthy persons. At the same time the above plan promises more fully, than any other yet devised, a satisfactory solution of this vexed problem. The managers of the German Dispensary have earned the thanks of the entire community for their pioneer work in charity reform.—Ed.]

INACCURATE URETHRAL INSTRUMENTS.

To The Editor of The Medical Record.

Sir: Inaccuracy in all things is lamentable, but particularly so in the manufacture of urethral instruments; for with these we not only perform the operation, but also trust to their correctness for measuring the amount of gain accomplished.

Recently I purchased, from one of the most reliable makers in New York, a number of urethral instruments. I will relate some of my experiences with them.

Take for the first instance the urethrometer of Otis. Mr. S—— came to my office with a stricture. After locating it, by means of a bulbous sound, at a distance of 85 mm. from the meatus, I introduced the urethrometer beyond the stricture and screwed it up to 44. Drawing it forward until arrested, I slowly lessened its circumference until it slipped through at 41. I then entirely withdrew it at this figure. Upon my taking up a No. 40 steel sound, the patient became alarmed at its size, but was assured by me that it would pass the stricture without causing pain. He believed me—I attempted to pass it and failed utterly. This did not inspire him with any undue confidence in me.

Second case in point. With an Otis' dilating urethrotome I divided a stricture of 25 calibre, 11 ctm. from the meatus, in a penis 85 mm. in circumference, indicating a normal calibre of 34 for the urethra. The stricture at a depth of 11 ctm. was the deepest and smallest, there being two between this and the meatus, which was also constricted. With difficulty I screwed my instrument up to 30, and then cut. Hiding the knife again I screwed it up to 36 and cut a second time. As the stricture seemed to be thoroughly divided, I withdrew the urethrotome and attempted to pass a bulbous sound, No. 34. This was arrested by the stricture, not by the smaller calibre of the urethra beyond; for, with a little force, it would slip through and beyond the stricture and be held slightly upon withdrawal. I then took up my divulsor, Gouley's modification of Thompson's, and engaging the most expansile part opposite the seat of stricture, screwed it up to 40. Alas, how uncertain are our conclusions based upon the calculations of others! That divulsion upon subsequent measurement proved to be incapable of attaining a greater size than 36! Please notice the actual size of the bulb further on.

Now, as regards the urethrometer, it proved to be so wretchedly inaccurate that I exchanged it for a much more expensive instrument which was nearly exact. The fact that the first one was not elaborately finished in gold plate was no excuse for its incorrect registering.

The urethrotome seems to have been measured at a distance of 15 ctm. from the dial-plate, when the lines indicating the amount of expansion were engraven thereon. These measurements should have been taken at the point where the knife first fully emerges. To illustrate: When the hand on the dial indicates 20, the knife emerges upon a circumference of only 17 mm. In the following, the first number of each couplet shows the indicated circumference, the second the actual measurement where the knife appears: 25–20; 30–25; 35–29; 40–35; 45–42. Surely this instrument is not all that could be hoped for.

These faults in construction led me to measure carefully my conical steel sounds by the same maker, and my bulbous sounds by another reputable maker. The steel sounds were usually correct within a millimeter. The 34 and the 40, however, measured respectively 36 and 42 mm. in circumference. The bulbous bougies were worse. No. 20, for instance, measured 22 mm.; 25, 27 mm.; 34, 37 mm. No. 40 measured nearly 43 mm.

From the facts here stated each can draw his own conclusions.

The question comes up, Where and how can we obtain correctly made instruments?

There is only one way to get them. Take nothing on faith, but carefully measure every instrument before purchasing, and refuse all that are not absolutely exact.

WARREN C. SNEDEN, M.D.

BROOKLYN, N. Y., April 22, 1885.

SURGERY IN THE HERMIT KINGDOM.

A PRINCE WHO RECOVERS FROM SEVEN WOUNDS, SYPHILIS, AND A TAPE-WORM — GUNSHOT WOUNDS — THE ENDURANCE OF THE COREANS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Happening to come to Corea just before the recent *emeute*, I was called in to attend the wounded Prince Min Yong Ik, recent ambassador to America. I was also given charge of the wounded Chinese soldiers, some twenty in all. And thinking that some of these cases might be interesting to the readers of THE RECORD, I will briefly notice some of the principal ones.

Prince Min was cut by a sharp Japanese sword on the night of December 4th in seven places. The principal wound was made by a vertical, somewhat slanting blow. The cut commenced on the temple, midway between the external canthus of the right eye and the ear of the same side. The temporal artery was divided, the ear split longitudinally and cleanly, one-half lying back on the hair of the head, the other upon the face. Extending downward along the course of the sterno-cleido mastoid, the external jugular was laid bare but uninjured. Lifting the platysma myoides for about half its breadth, the wound continued down the back to a point on a level with the lower angle of the scapula, and midway between it and the spinal column, ending with a curved point where the sharp instrument left the flesh. The cut was two inches deep in the muscles of the back, but the only severe hemorrhage was from the divided temporal artery. The other wounds were upon the scalp, the mastoid, the arms, and the thigh.

I tied the temporal artery, cleansed all of the wounds with carbolic solution, 1 to 40, dressed them with iodoform, and put in twenty-two silk and five silver sutures. Having to be moved about from place to place for safety, the wounds began to gape and suppuration took place in all but the wound to the ear itself. His temperature ranged between 101° to 103°, with occasional chills, until January 1st, when it fell to 100°, and did not rise so high again.

The daily dressings were with cotton-wool soaked in carbolic solution, 1 to 20, and were changed daily because of the discharge, excepting only those of the ear and the scalp, which were not removed till the wounds had healed.

Some peculiar things occurred during the treatment. One was the dosing of the patient with strong infusions of ginsing—the native panacea. This was done by his friends without my knowledge, and I only discovered it when trying to ascertain the cause of a rise of temperature that was not accounted for by any fresh inflammation.

Another thing was his great persistence in taking soup made of dogs' flesh and dogs' heads. This was done without my sanction. Yet, as his appetite became so poor, I thought it best not to interfere too much with his accustomed diet. (Dog flesh is always for sale in the shops, and though not eaten continually by all, yet there is not an adult native in the country who has not eaten more or less of it.) I was not much surprised at the appearance of segments of tape-worm in his stools; but became surprised at his unconcern regarding it. It was with difficulty that I induced him to take the turpentine and castor-oil that eventually cured him. Since then I have been examining stools along the streets, and find pieces of tape-worm *very* common, which accounts for the unconcern.

Aside from the common and ever-present syphilis, which came in as a complication, as it does in almost all disease among the Coreans, the only other thing of importance was the development of marked facial paralysis of the wounded side. It came on a few days after the injury, leading me to suppose it to be due to consequent inflammation and swelling, rather than to division of the nerve. I was strengthened in this belief by the fact that the paralysis came on in sections, so to speak, the cheek and mouth being the parts first affected. The temporo-facial branch seemed unaffected till late, as I could see no tendency in the eye of that side to remain open, until about thirty days after the injury, when it became painfully and obstinately open. At the same time I found swelling over the parotid gland, which eventually broke down into pus and necessitated an external opening, the affection of the eye decreasing therewith. The tongue never deviated perceptibly, though there was abundant swelling about the stylo-mastoid foramen, and it would seem difficult for the lingual branch to escape being pressed upon. His recovery has been good.

Among the Chinese soldiers there were of gunshot wounds—of thigh, two; groin, one; foot, one; forearm, three; abdomen, three; hand, two; eye, one; and gluteus, one; bayonet wound of abdomen, one; wounds from explosion of powder mine—of leg, two; of hand, one; one sword cut of calf, and a bayonet wound of neck.

There were three cases for amputation—one of the hand, two of the forearm—but in no case would they let me use a knife. In one case, however, that of a clean shot in the eye, I performed excision without asking permission, and he has made a good recovery, with no sympathetic trouble. I did not see the above-named cases of wounds to the abdomen until three days after the injury, and in no case was there marked general peritonitis. The only death was one of the cases of wounds to the forearm, where amputation was not permitted. He died of tetanus on the eighth day after the injury, third day of the spasm. All the rest of the cases recovered either completely or sufficiently to be removed to their men-of-war. These cases well illustrate the power of endurance among the Orientals, and especially is this a fact with two of the cases which I wish to mention more fully.

In the gunshot wound of the groin the ball entered just below Poupart's ligament, and about an inch outside of the external ring, on the left side. It came out at about the centre of the buttock on the same side, and must have pierced the bone without much splitting. When I first saw him, twenty-four hours after the accident, he had the skin of a dog, freshly killed, on both wound of entrance and exit. As it made an excellent poultice I left it on for the first day, and then poulticed it for the next three days with hot rice. After which I applied small bags of pulverized yellow clay, simply as an absorbent and disinfectant, being without anything better. The man went on rapidly to recovery with no untoward symptoms, until on the twentieth day from the receipt of the injury he was walking about. He now rides a horse and attends to his duties as a colonel in the Chinese army.

The bayonet wound of the neck was ugly indeed. The Japanese have a relic of barbarity in their great sword-toothed bayonets. One of these had been thrust through this man's neck, entering just below the angle of the jaw, on the right side, and coming out at the back, almost piercing the ligamentum nuchæ. When the weapon was withdrawn it tore away a piece of flesh three inches by two and a half. I thoroughly cleansed the track of the wound with carbolic solution, 1 to 40, and applied pressure; the raw surfaces were dusted with iodoform, and the whole covered with cotton-wool soaked in carbolic acid. To my great surprise this man improved almost daily, and at the end of six weeks had only a small cicatrix left over both wound of entrance and exit. Morphia was given liberally in all these cases, and as their pain was relieved and they had enough to eat, probably the resulting state of contentment had much do with their

speedy recovery. . . . I may add that the Coreans use more hearty food and more strong alcoholic drinks, causing them to be more liable to inflammations than the Chinese. Yet they can hold their own pretty well, as is illustrated by a case which has just come to me. I may add the Coreans seem to appreciate what has been done for them by Western medical science, and among other presents the King has given me a large house and compound for a hospital, with money for equipment and annual expenses.

H. N. Allen, B.S., M.D.,
Physician to the Legations, the Presbyterian Mission, and in charge of the Royal Corean Hospital.

Seoul, Corea.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 29, 1885, to June 6, 1885.

Horton, S. M., Major and Surgeon. Ordered for duty as Post Surgeon, Fort Riley, Kansas. S. O. 78, Department of the Missouri, June 1, 1885.

Cleary, P. J. A., Major and Surgeon. Ordered for duty as Post Surgeon, Fort Lyon, Colorado. S. O. 78, Department of the Missouri, June 1, 1885.

Brown, J. M., Major and Surgeon. Assigned to duty as Post Surgeon at Fort Omaha, Nebraska. S. O. 49, Department of the Platte, May 29, 1885.

Brechemin Louis, Captain and Assistant Surgeon. Relieved from duty at Fort Omaha, Nebraska, and assigned to duty as Post Surgeon at Fort D. A. Russell, Wyoming. S. O. 49, Department of the Platte, May 29, 1885.

Ainsworth, F. C., Captain and Assistant Surgeon (Department of Texas). Ordered for temporary duty in Department of the Missouri. S. O. 58, Department of Texas, May 25, 1885.

Porter, Jos. Y., Captain and Assistant Surgeon. Granted leave of absence for six months on account of disability. S. O. 126, Adjutant-General's Office, June 3, 1885.

Davis, William B., Captain and Assistant Surgeon. Granted leave of absence for one month, from May 25, 1885. S. O. 122, Adjutant-General's Office, May 28, 1885.

Robertson, R. L., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 123, Adjutant-General's Office, May 29, 1885.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 6, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
May 30, 1885	3	11	76	4	97	87	1	0
June 6, 1885	4	13	71	4	100	70	0	0
Deaths.								
May 30, 1885	0	4	11	5	14	27	0	0
June 6, 1885	1	3	16	3	12	26	0	0

Diphtheria as I See and Treat It.—Dr. T. J Hutton, of Fergus Falls, Minn., significantly writes: "Like the Peoria specialist who considered urinary examinations essential in the treatment of all diseases, many of our city brethren harp on sewers and sewer-gas as the sole cause of diphtheria. Now, sewers do contain human detritus, and they, doubtless, may originate diphtheria, but this detritus must not necessarily pass through sewers in order to cause it. The nearest sewer was two hundred miles distant from every case treated by me. Carpenter says the Arabs of Sahara can smell a fire thirty to forty miles off, and Humboldt says the Peruvian Indian can smell the approach of a stranger in the darkest night, while yet far off, and can also tell with certainty whether it be a white, a negro, or an Indian. To believe these statements is a severe strain on our credulity, but to believe that either savage or civilized beings can draw into their nostrils the small end of a sewer at a distance of two hundred miles seems to me simply too transcendental, or too ridiculous, I can hardly tell which."

The Reporting of Contagious Diseases—A Suggestion to the Board of Health. — Dr. J. W. Brannan, of this city, makes the following very sensible suggestion: "I see by the last Record that the Board of Health complain that many physicians do not report promptly their cases of contagious disease. I would suggest to our Health Board that if they would simplify the work of reporting there would probably be less neglect of the regulations on the part of physicians. In Boston all physicians are provided by the local authorities with postal cards, on one side of which is printed the address of the Board of Health, and on the other very much the same form of words that is found on slips furnished to physicians in New York. In a case of contagious disease, the blank spaces in the form are filled out, the card is dropped into a post-box, and the matter is over. I commend the above plan to our Board of Health, that they may secure greater efficiency of service."

Evacuation of an Ovarian Cystic Tumor through the Intestines.—Dr. H. W. Carpenter, of Oneida, N. Y., sends us the following interesting case: "Mrs. C. A——, aged thirty-two, married, and mother of three children, began to decline while nursing her child, which was about one year old. I first saw her with her physician July 3d, and found her suffering from pain in back and right side. No appearance of tumor. Saw her again September 5th, and then found a right ovarian tumor, about as large as a child's head. Her general appearance indicated disease; she was very weak and melancholy. Her physician had suggested that she go to New York for treatment, but she and her friends thought her too weak to bear the journey. She remained under his care till some time in January, when she commenced treatment with a doctor in Syracuse, who made an attempt to remove the dropsy by powerful diuretics. She constantly grew worse, and gave up all hopes of living, and early in February, Dr. Ure, living but a short distance from her, was called, who requested me to see her with him She was then very much emaciated; the abdomen being enormously distended. There was marked peritonitis on left side with general cyanosis; and she was nearly pulseless at the wrist; respiration labored and forty-five per minute. We were in some doubt whether surgical interference would be of any avail, but concluded the only hope of prolonging life would be to remove the contents of the sac, which we accordingly did, taking away thirty quarts, and a careful examination showed it to be seventy-five per cent. albumen. She rallied nicely after the operation, and in about six weeks there was perforation of the colon, as near as could be ascertained, at the sigmoid flexure, and the fluid that had slowly accumulated in the sac was discharged per rectum, and on May 15th the entire sac passed off. Very soon after the perforation the patient began to improve in strength and flesh, and is now able to ride five or six miles without becoming tired. With the exception of slight pain in the right iliac region she says she feels perfectly well."

Original Lectures.

A LECTURE ON THE USE OF THE OPHTHALMOSCOPE IN MEDICAL DIAGNOSIS.[1]

By HENRY JULER, F.R.C.S.,

OPHTHALMIC SURGEON TO THE ST. MARY'S AND THE ROYAL WESTMINSTER OPHTHALMIC HOSPITALS, LONDON.

GENTLEMEN: The subject I have chosen for this lecture cannot, I think, fail to be of interest to you all, whether engaged in the wards of the hospital or in general practice. Inasmuch, however, as some of you may be unaccustomed to the use of the ophthalmoscope, and, therefore, unacquainted with normal appearances of the fundus oculi, I will first call your attention to the three chief methods of using the instrument; I will next describe the ophthalmoscopic appearances of the healthy eye, and then proceed to relate a series of cases which have occurred in my own practice, illustrative of the advantages in diagnosis accruing to the routine practice of ophthalmoscopic examination.

The three chief modes of examining the fundus are: 1, The direct method; 2, the indirect method; 3, retinoscopy, or the shadow-test.

In the direct method the eye of the observer with the mirror in front of it should be placed as closely as possible to that of the patient, so that the distance of the mirror from the cornea of the latter is only about one centimetre. The lamp should be just above and to the outer side of the patient's ear, right or left, according to the eye examined. By this means we are enabled to look directly at the fundus oculi. In order to understand this it is only necessary to consider the rays which emerge from the patient's eye, and to imagine the observer's accommodation relaxed. We know, in the first place, that in order to get distinct vision when the accommodation is relaxed, the rays from the object looked at must be parallel. Now, in the emmetropic eye the emergent rays are parallel, and so we see the fundus clearly and distinctly without the use of a concave or convex lens. In the myopic eye, however, the emergent rays are not parallel but convergent, and so we cannot clearly see the details of the fundus without the use of a concave lens such as shall render the convergent rays parallel. In hypermetropia again, the emergent rays are not parallel but divergent, so that we can only see the fundus by the use of a convex glass of such strength as shall render the rays parallel. For the successful use of the direct method, therefore, we require the use of a *refraction* ophthalmoscope, that is, of an instrument such as I here show you, which is provided with a series of concave- and convex-spherical lenses, which can be made to revolve in front of the sight-hole of the mirror.

By the indirect method we examine the inverted image of the fundus. On placing a strong convex lens (about 13D) in front of the patient's eye, the emergent rays are brought to a focus so as to form an inverted image in the air. It is this image which is seen through the sight hole of the mirror. As a ready method this is extremely useful, but for minute examinations it is far inferior to the direct method.

By the shadow-test, or retinoscopy, we have a comparatively recent method of examining the refraction of the eye. First, we stand at a distance of more than one metre from the eye, and then, by projecting the light from a lamp placed above the patient's head, we illuminate a circular area of the fundus. The circular outline of this illuminated area is caused by the pupil; its dark border is therefore the shadow of the iris. Now, if we very slightly tilt the mirror while looking at the illuminated fundus, so as to project the light from above downward, or in any other meridian, we observe one of three conditions, according to the refractive condition of the eye examined. In the first place, a mere movement of light and shade passing in the opposite direction to that of the mirror, but having no distinct line of demarcation between the light and the shade, indicates emmetropia; secondly, a distinct linear edge to the shadow which moves in the *same* direction as the mirror, denotes *myopia;* and thirdly, a definite linear edge moving in the *opposite* direction, is a proof of *hypermetropia.* Thus, by a mere glance with the ophthalmoscope, and without the least trouble either to ourselves or to the patient, we can say whether there is emmetropia, myopia, or hypermetropia. And, finding an error of refraction, we can almost as easily estimate its amount. To do this, we have simply to place concave or convex glasses in front of the examined eye until the said shadow disappears. The strength of the glass thus required to neutralize the shadow is the exact expression of the amount of ametropia.

The next point to which I would ask your attention is *the appearance of the normal fundus.* This is best seen by the direct method of examination. By the exercise of a very little mechanical ingenuity we can easily explore the greater part of the area of the fundus. The first object to attract attention is usually the optic disk. This is a circular, somewhat moon-like structure, situated a little to the nasal side of the posterior pole of the eye; it is also called the papilla and the blind spot. From the optic disk we see radiating the retinal vessels; these are mainly two arteries and two veins, curving upward, and the same number curving downward, each giving off branches in its course. These vessels can be followed nearly as far as the periphery of the fundus, where they terminate; but remember that the finest ramifications—the capillaries—are not visible. At the posterior part of the eye, about two diameters distance outside the optic disk, we notice an absence of visible vessels. Sometimes there is an intensification of the red color of the fundus here, and occasionally there is a yellowish appearance; this is the yellow spot, the most sensitive portion of the retina. In examining, then, we first note the optic disk, which should be of a pale pink tint as contrasted with the surrounding color of the fundus. Sometimes, however, we find that in healthy eyes the disk has a very whitish appearance, similar to that found in primary atrophy of the optic disk; and we must always look with suspicion upon a pallor of the disk until, by careful testing, we find that the visual field is of normal dimensions, and the visual acuteness up to the normal standard.

Another condition sometimes found in healthy eyes is that of a depression or cupping of the central part of the disk. This differs from the cupping of glaucoma in the fact that the latter involves the whole area of the disk, while the *physiological cup* is only caused by the fibres of the nerve diverging from the level of the lamina cribrosa.

Another non-pathological appearance which we ought

[1] Delivered at the Royal Westminster Ophthalmic Hospital, London.

to mention here is that of opaque nerve-fibres; these are white fibres of various forms, radiating from the disk and partly obscuring the retinal vessels. They are caused by the persistence of the medullary sheath of the fibres of the optic nerves, which, as a rule, ceases at the lamina cribrosa. The outline of the blood-vessels should be clear and well defined, they should be thickest at the disk and gradually taper toward the periphery. The veins are slightly larger and a little darker in color, as well as a little more tortuous, than the arteries. The red reflex of the whole fundus, as seen with the ophthalmoscope, is derived from the blood in the vessels; or, rather, in the capillaries of the inner part of the choroid—the chorio-capillaris—this is modified in degree by the amount of pigment existing in the pigment-layer of the retina. In the albino the amount of pigment in this layer is almost nil, and we find the reflex to be of a light red color, while the choroidal vessels are plainly visible. In blondes there is also very often a deficiency in the amount of pigment. In dark persons it is usually copious, and the red reflex presents a darker and more brown-red appearance; while in the negro and all dark races, the reflex is very dark. It should also be remembered that the retina itself is invisible in health; with a few exceptions, this structure may be compared to a layer of plate-glass spread out in front of the choroid, its only visible structures being the retinal vessels and the posterior or pigment layer. Now and then we observe a slightly wavy "shot-silk" appearance over the whole retina, and occasionally, in children, the immediate vicinity of the optic disk presents a radiate striation of the retinal nerve-fibres; but with the exception of the opaque nerve-fibres just mentioned, these constitute the only varieties of opacity of the retina in health. I will now pass on to the consideration of a series of cases, which I promise shall be such as may any day present themselves to your notice in the course of future practice.

Case I.—A young woman, aged twenty-three, well developed but somewhat pale, came to the Westminster Ophthalmic Hospital, complaining of dimness of vision and violent pains in the head. Her friends who accompanied her were much alarmed, and stated that she had had several severe "fits," in which there was loss of consciousness and severe struggling for more than an hour each time. Being a specialist, my first step toward making a diagnosis was to make an ophthalmoscopic examination, by which I found the fundus and the refraction of the eye to be quite normal, *i.e.*, by retinoscopy there was no distinct shadow having a linear edge, and by the direct method of examination the disk presented its normal pink tint; it was not hazy or swollen, the retinal vessels were clear in outline, no white spots could be seen in the retina, nor any red streaks indicating hemorrhage from the retinal vessels; in fact, the eyes were perfectly normal in every detail.

I now proceeded to examine the vision, and with a little ingenuity in taking the patient unawares, I found that the vision was quite up to the normal standard, and that the dimness complained of was imaginary. On further examination of the case, I found that other functions of the body were intact, and that the convulsive seizures described by the friends were of the hysterical type. The patient was given to much crying, and became worse in proportion to the amount of sympathy received. I concluded, therefore, that the case was one of simple hysteria, and was able to adopt appropriate moral and other treatment, and to give a favorable prognosis. From an ophthalmoscopic point of view, therefore, the case was a negative one, and you will probably be inclined to say that any practitioner of ordinary intelligence could have arrived at the same result without going through the form of using the ophthalmoscope. This I am prepared to admit, but I am convinced that the use of the instrument, even here, enabled me to proceed with more confidence in the examination, and to speak more decidedly as to prognosis and treatment. With pain in the head, anæmia, and dimness of vision, I should have been less certain without an examination of this kind, as the following cases will tend to show.

Case II. was at first sight not unlike the first. A young woman, aged nineteen, somewhat pale, but well developed, complained of dimness of vision and slight headache. Here the ophthalmoscope showed that, though the refraction of the eye was normal, the optic disk was hazy and obscure, its circular edge could no longer be seen by the direct method, and the central vessels were also rather obscure at their point of radiation; nor could they be made visible by the use of either concave or convex lens behind the sight-hole of the mirror. By the convex lens in that position, however, it was found that the hazy portion of the optic nerve could be seen with a convex lens of considerable strength (5 dioptrics), by which I was positive that this structure was much swollen. There were no red streaks of hemorrhage, nor yet any white spots, so that I knew I had to deal with a case of simple optic neuritis. On the discovery of so serious a symptom, I at once proceeded to a thorough general examination. No localizing symptoms could be found, *i.e.*, no paresis or spasm of any particular set of muscles, nor any hyperæsthesia, or loss of sensation in any part of the body. There had been no vomiting at any time. The only abnormal sign I could find was that the catamenia had ceased for some time. There was occasional headache, and the vision was slightly defective, being only $\frac{6}{12}$ of Snellen's types. The case was treated for the amenorrhœa, and the disappearance of this was accompanied by the disappearance of the double optic neuritis, improvement of the vision, and perfect restoration to health. Had I not used the ophthalmoscope in this case, I feel that I should have attached less importance to the cure of the amenorrhœa; yet, from my own experience, I consider this to be typical of a large class of cases in which optic neuritis is brought about by derangement of the menstrual function, and which are likely to terminate in absolute blindness from optic atrophy, unless that function be restored to a healthy condition.

Case III.—Another case in which optic neuritis was detected by means of the ophthalmoscope is that of Annie B——, aged ten, a delicate child. She had suffered from measles five months before coming under my notice, and, since her convalescence from the measles, had complained of gradually increasing failure of vision, and headache. When I first saw her, three years ago, she could only read large types ($\frac{6}{18}$ and No. 3 of Snellen). On examining with the ophthalmoscope, I found both the optic disks very much swollen and hazy; there were no hemorrhages, nor patches of exudation, but the outline of both disks was lost, and there was evident optic neuritis. By further examination with the shadow-test, I found that the eyes were ametropic; there was compound hypermetropic astigmatism in each. I was also gratified to find that the correcting-glass caused improvement in her vision in spite of the optic nerve inflammation; this restoration was not complete, but still was considerable ($= \frac{6}{12}$ Snellen). No other cause for the optic neuritis could be found; there were no symptoms of intracranial disease, nor anything else beyond bad vision, anæmia, and frontal headache. I have seen the patient quite recently, and am glad to say that her vision is almost completely restored, the optic disk is not atrophied, but presents a slight haze, and the girl's health appears excellent.

This case appears to me to present many points of interest. In the first place, we could not have ascertained either the ametropia or the inflammatory swelling without the aid of the ophthalmoscope. Secondly, astigmatism is not, so far as I am aware, a recognized cause of optic neuritis, although my conviction is that this is by no means an uncommon occurrence.

Case IV.—A medical man, thirty-eight years of age, of powerful physique, active habits, and literary tastes,

consulted me upon a matter which, to him, had for several years been a source of the greatest trouble and anxiety. He stated that his left eye had become useless, and that he had been told, by a competent authority, it would not improve; that his right eye was now becoming so dim that he could not read at night, nor, indeed, had he courage to read more than a little by day. He wore smoked glasses by way of precaution. He had been told that tobacco-smoking was the cause of his malady, and he had consequently relinquished this, his only weakness.

Besides this history of gradual failure of vision, he suffered from frontal headache on attempting to read, and I must say I thought his case sounded somewhat serious as it was thus related to me.

My first act, however, in the way of diagnosis, was to apply the shadow-test, and, looking at the left—the worst eye—first, I found hypermetropia of three dioptrics, and further, by the direct method, I found the optic disk congested. The right eye was also hypermetropic, although to a less degree, and the disk here also hyperæmic. Having corrected the ametropia of both eyes by the same shadow-test, I found that his vision was rendered quite normal by the correcting-glass, and you can perhaps imagine the delight of this man when I was able to assure him that he had no tobacco-amaurosis at all, and that he might use his corrected eyes *ad libitum* without further fear or trembling.

This, then, is another case which is typical of a very extensive class, where by the ophthalmoscope alone we can discover and relieve a troublesome malady, and one which is frequently shirked by the general practitioner, or is altogether misunderstood.

I have known numbers of cases where ametropes have been advised to desist from all studies, to change their vocation in life, to go abroad in search of recreation, when all that was required on the part of the practitioner was a single glance with the ophthalmoscope.

Case V.—A woman, twenty-five years of age, came to St. Mary's Hospital, complaining of dimness of vision. She was fairly nourished, but suffered from lassitude and general weakness. As the vision was chiefly complained of, I made an ophthalmoscopic examination. By the shadow-test there was no error of refraction, but by the direct method it was impossible to see the optic disk; this was quite blurred, as if by a dense mist. The condition was one which might easily be mistaken for inflammation and swelling of the nerve, but, upon using a convex lens behind the sight-hole of the mirror, and directing the patient to move the eye sharply upward and downward, I noticed numbers of fine, "dust-like" particles, which continued to move about after the eye had come to rest; the periphery of the fundus was fairly clear and visible. The opacity was chiefly in the vitreous, toward the posterior pole of the eye. Upon further examination of the case, I found that the patient's hair came off freely in brushing, that the throat was red and presented patches of "mucous tubercle." On the chest and abdomen I found a subdued roseolous rash, and by dint of judicious interrogation, I at last ascertained that a chancre had recently existed on the labium.

There was no inflammation of the anterior parts of the eye, no iritis, no visible choroiditis. It was one in which a cloudy opacity of the vitreous is indicative of constitutional acquired syphilis. I have seen many such cases, and I think it worthy of bringing before your notice, because the ophthalmoscopic examination has been the means of giving the cue to the general diagnosis. I have at present three women and one man under treatment, in all of whom I discovered the general disease through this local symptom. Although I do not mean to infer that in all cases of constitutional syphilis we find dust-like opacities of the vitreous, yet I maintain that this is often indicative of that affection, and so becomes a useful diagnostic sign.

Case VI.—A lady, aged forty, consulted me for twitching of the right eyelids. I noticed also that the mouth was drawn somewhat to one side, that there was partial hemiplegia, and that the vision was defective. On using the ophthalmoscope I found both the optic disks intensely swollen, the retinal vessels were tortuous, the arteries being scarcely visible in parts, and the veins distended to twice their normal size; there were also numerous torch-like red streaks radiating from the centre in the direction of the vessels; these were retinal hemorrhages. This was a case which, of course, I had no hesitation in pronouncing to be one of cerebral tumor, but many have come before my notice in which the optic neuritis was one of the earliest signs of the intracranial disease. The other symptoms are very varied, and it would be impossible for me to describe them in this lecture; but I would take this opportunity of stating that, wherever double or even single optic neuritis is discovered, it is our duty to give a most guarded prognosis. Very much has yet to be made out in the diagnosis of intracranial affections, but I am confident that the ophthalmoscope will continue to be of the greatest service in that direction. In an excellent discussion upon optic neuritis in intracranial disease, which took place at the Ophthalmological Society in 1881, Dr. Hughlings-Jackson says, "Good health goes for nothing in our estimation of the gravity of the situation in many cases of optic neuritis, even when the sight is good. We all see healthy-looking, robust children and adults, who have double optic neuritis with good sight, who are sometimes supposed, by those who do not use the ophthalmoscope, to have no intracranial disease at all. Some of these patients nevertheless have intracranial tumor. Sometimes death occurs rapidly and unexpectedly;" and further on, when speaking of optic neuritis with headache and vomiting, he says, "The headache is intense; often it is paroxysmal, the patient being in the intervals apparently quite well. The vomiting is purposeless and bile is often brought up. Hence the frequent, almost invariable diagnosis in the early stages of chronic cases of cerebral tumor (when the sight is good or only defective), of liver derangements, and in acute cases the occasional diagnosis of bilious and gastric fever." Some years ago Mr. Hutchinson wrote as follows: "The symptoms headache and vomiting very often indeed occur when there is neuritis without defect of sight; the patient in the intervals of his pain may go about and even transact his business. He is supposed to be only bilious, or sometimes, if a woman, only hysterical, until some unmistakable intracranial symptom, such as convulsions, suddenly alters the diagnosis." . . . "The routine practice of the ophthalmoscope would save us from many of these errors. No one would make the diagnosis of liver disease, nor of hysteria, only if, looking at the disks, he saw neuritis."

Case VII.—Daniel M——, thirty-nine years of age, came to St. Mary's Hospital, complaining that he had not felt well of late. He had had occasional bilious attacks, but he thought he could do his work if his sight were not getting so defective.

On ophthalmoscopic examination I found the optic disks quite hazy, old and recent hemorrhages scattered about the retinæ, numerous white deposits free from pigment in the region of the yellow spot and round the periphery of each fundus. His vision was very bad, being only equal to $\frac{6}{24}$ of Snellen. The man was in great trouble, being the possessor of a wife and four children who depended upon his labor for their existence. He had been several months under medical treatment, but had never been told that his kidneys were affected.

My first glance at the fundus of this case convinced me that the man was the subject of albuminuria, and on testing the urine we found it loaded with albumen and to contain numerous granular casts.

Here, then, is another example of a large class of cases where the use of our ophthalmoscope enables us to detect a general disease. Had it been used earlier by the general practitioner, the kidney affection would per-

haps have been more fully realized and more promptly treated. I have known many such. My friend, Dr. Sydney Phillips, was telling me the other day of a very interesting case of this kind which occurred in his experience.

A woman, six months advanced in pregnancy, applied at Moorfields Hospital on account of bad vision. She was examined with the ophthalmoscope and found to have albuminuric retinitis. The vision becoming very bad, and the albuminuria being considered due to pregnancy, she was advised to have premature labor induced. After submitting to this treatment her sight returned, and the albumen disappeared. She was cautioned as to the danger of future pregnancy, and remained quite well for several years, when she again became pregnant with precisely similar results, and had to go through the same process in order to prevent absolute blindness.

This completes the list of cases I intended to bring before your notice to-day, although there are many others of great interest and of equal importance, which, if time permitted, I could have quoted, to show how much help may sometimes be obtained from the early and routine practice of the ophthalmoscope.

For instance, in that widespread and often obscure affection known as locomotor ataxia or tabes dorsalis, I very frequently discover the spinal affection through abnormal pallor of the optic disk.

In many cases of delirium, again, where there is pyrexia, brown tongue, and perhaps semi-dilated pupils, it is often difficult to establish a definite diagnosis; but if we find a woolly optic disk, or could detect the existence of white hemispherical spots in the fundus, this would be strong evidence in favor of the existence of tubercular meningitis.

In cases of anæmia, again, such, for instance, as those described in Cases I. and II., or perhaps more marked than these, if the opthalmoscope revealed the existence of retinal hemorrhages, this would be the signal for the greatest care and anxiety lest the case should assume the malignant type of this affection, and the prognosis in such a case must be guarded indeed.

Original Articles.

A FEW PRACTICAL REMARKS ON RUPTURE OF THE PERINEUM.

By FRANK HASTINGS HAMILTON, M.D., LL.D.,

NEW YORK.

This accident is of quite frequent occurrence, especially in the birth of the first child. It is unjust to say that it can always, or even generally, be prevented by the skill of the accoucheur, since its occurrence is often due to conditions and circumstances over which the accoucheur has no control. The perineum may be unusually deep in its antero-posterior diameter, or unusually thin and delicate, or less elastic in its texture than natural; the sacrum and coccyx may not have the proper curve to direct the head toward the pubes; the head itself may be large and unyielding; the uterine contractions may be too violent and rapid to allow the perineum time to become gradually stretched and accommodated to the head. Indeed, there are many causes which may determine this result which are wholly beyond the power of the accoucheur to remove.

Obstetricians have frequently given instructions how to avoid the accident, and have sometimes intimated that its occurrence always implied negligence on the part of the accoucheur. It has been advised to insert two fingers between the head of the child and perineum and stretch the perineum; but the advice has been very properly rejected as unphilosophical and useless. The fingers are more liable to cause a laceration than would be the head of the child. To make two lateral incisions, when a rupture seems imminent, is to make an operation which may have been unnecessary.

Most commonly the advice given is to "support" the perineum by the palm of the hand, or by the hand with a folded napkin interposed. Precisely what is meant by the word "support," as here used, is not always clearly stated, but in general we are left to infer that the writer intends to say, that by this outside superficial pressure the perineum is reinforced and strengthened, and its liability to rupture is lessened.

I will venture to say that the idea cannot be sustained by any sound mechanical theory, or by experience. I have myself given "support" in the manner described, with the naked hand, but not for the purpose above indicated; and in the last efforts of labor, when the perineum had become as thin as a sheet of writing-paper, I have felt it suddenly give way under my finger, the rent commencing in the centre of the concave edge, and extending backward more or less as the head passed out. I am certain that no mechanical aid or human skill could have prevented this result. Said the late Professor Elliott: "The perineum can always be saved from laceration when the camel can go through the eye of a needle."

If the intention is to delay the advance of the child, a theory which at least one teacher of obstetrics has maintained in a public discussion in my presence, the intention is a good one, but the method of seeking to accomplish it is of no value. No resistance, or none which could ever be considered justifiable, applied to the perineum, can appreciably delay the advance of the child when the uterus is acting with its normal or with unusual vigor, and under no other circumstances would it be required.

According to Velpeau ("Midwifery," Amer. ed., p. 349), the accoucheur of the public lying-in hospital at Gottingen, in 1830, and "the one who in 1824 directed the lying-in hospital of Dublin," were of opinion that these attempts to give support were all useless, and that they were even dangerous—an opinion which is probably correct unless the pressure be applied only for the purpose next to be indicated.

Finally, if the purpose of making pressure upon the perineum is to carry the head forward toward the pubes, the suggestion has a meaning and can be understood. Certainly this is advisable whenever, from the lack of curve in the sacrum and coccyx, or from any other cause, the vertex does not take this direction; but these examples are rare and exceptional.

It does not follow, from anything I have said, that the accoucheur might not sometimes be responsible for this accident, but his responsibility is likely to consist in what he may actually have done rather than in what he may have omitted to do. A lacerated perineum is caused sometimes by the improper haste of the accoucheur. He has been unwilling to wait upon the tardy processes of nature, or until the parts have become sufficiently dilated, and he has sought to hasten labor by the use of ergot or some other similar agent, or he has unnecessarily resorted to the use of instruments. Gooch ("Midwifery," American edition, p. 55), speaking of a serious rent of the perineum, says it is rare, "except during the application of the forceps, when," he says, "it is not an uncommon occurrence." Some modern gynecologists do not think the danger of rupture of the perineum is increased by the use of the forceps, if only they be used skilfully; but it certainly must increase the danger if the instruments are used unskilfully; and when, in the hands of the most skilful, the instrument is retained in position until the head has entirely escaped from the vulva. Nor does it appear to me that the argument in their defence is conclusive, even when they are only employed to bring the head into the lower strait, and then withdrawn, leaving nature to complete the delivery, as I think is now the general advice and practice of accoucheurs. It is claimed that by this simple manœuvre the process of natural labor may often be greatly expedited; but this is the very thing which it is generally most desirable to avoid, so that, as Meigs says, the perineum may "not be taken by surprise." In short, there is less

danger to the perineum when the head does not come upon it forcibly and unexpectedly, and before the head itself has undergone the process of moulding and elongation.

But there are other evils than a lacerated perineum, which are apt to follow a too rapid delivery, such as sudden inertia of the uterus, post-partum hemorrhage, detention of the placenta, and septicæmia. It has seemed to me that these accidents were more frequent after too rapid delivery than after those which have been too much delayed; but these are points which are not relevant to the subject under consideration, and which I do not propose now to discuss.

I may be permitted, however, to refer to the fact that, since the time when I commenced the practice of medicine, the question of instrumental labor has undergone a complete revolution. I was a pupil of Dewees, and was taught that the forceps were seldom required; but to-day the teaching is altogether different, and there are now many gynecologists who count their instrumental labors by the thousands. A young man who was urging me to apply the forceps to his patient, but in which case the result proved that it was unnecessary, told me that a friend of his, a recent graduate of one of our city schools, and who was doing a large obstetrical practice in a neighboring town, assured him that he never put a woman to bed without forceps. I do not hold this young man's teachers responsible for his practice, but the fact illustrates what is now the drift of professional opinion.

If the obstetrical experience of my early life, and the surgical experience of my later life, have not misinformed me, grave perineal lesions are more common now than formerly, and this increase has been coincident with the increased use of forceps and of anæsthetics in labor. I mention anæsthetics in this connection, because the forceps and anæsthetics are so often associated in modern practice. The effects of anæsthetics are by no means in all cases limited to the alleviation or abolition of pain when employed in the case of the parturient female. In most cases they exert a positive influence upon the uterine contractions, and in this respect they are capricious. Sometimes they increase the frequency and strength of the contractions, and this is especially apt to happen when given in small quantities and in the first period of their exhibition; it is under these circumstances that they may contribute to the production of a perineal rupture. In other cases, under their influence I have seen the uterine contractions temporarily suspended, and a degree of uterine inertia induced which continued to the close of the labor, and which has been accepted by me in more than one instance to explain the delay in the expulsion of the placenta, and the subsequent uterine hemorrhages.

While there can be no question that the forceps and anæsthetics have been of incalculable service to parturient women, I have a strong conviction that, since they have come into such common and almost universal use, they have done a great deal of harm. I believe that the time is not distant in the future when it will become apparent to all that we have in these matters progressed too rapidly, and possibly that our progress has been altogether in the wrong direction.

In a large proportion of cases the rupture is slight, involving only the fourchette, or only the mucous membrane which has been thrust beyond the fourchette. In exceptional cases it involves a large part or the whole of the perineum, and still more rarely it extends directly, by laceration, or by subsequent sloughing, through the sphincter ani, and more or less extensively destroys the vagino-rectal septum.

In the simpler form of these accidents, where only the fourchette is torn, no serious injury is inflicted, and no surgical treatment is demanded. If left to itself, and some care be taken to keep the parts clean, it may be restored to its original condition by the unaided process of cicatrization; but if it is not thus restored, no future inconveniences to the patient will ensue. Indeed, this partial loss of perineum may render any further laceration in subsequent deliveries less probable.

In case, however, the laceration involves any considerable portion of the perineum, extending nearly, or quite, to the outer circumference of the sphincter ani, the closure of the rent is desirable, inasmuch as in a certain proportion of cases it is followed by a relaxation and falling of the vaginal walls, with a consequent displacement of the uterus. But it has often happened to me to see women, in whom the rent has extended through the entire perineum, who have after the lapse of many years suffered no inconvenience from this source. Especially has this been observed in the persons of spare women, and if they have not subsequently borne children.

The concurrence of a deficient perineum, and of prolapsus uteri, do not always stand in the relation of cause and effect. The perineum in its most perfect condition, and when the uterus occupies its normal position, gives no direct support to the latter. The uterus may be made to descend from many causes whether the perineum is sound or not; and if in its descent it has been brought into actual contact with the perineum, the presence of the latter is an important obstacle to its farther protrusion. The absence of the perineum, when the vagina and uterus are in their normal conditions, can only influence the descent of the uterus by first inducing atony of the muscular fibres of the vagina, with congestion and prolapse of the vaginal walls, by which not only the feeble and indirect support which the perineum gave to the uterus is removed, but the vaginal walls become actually a dead weight, to drag the uterus downward. These consequences to the vaginal walls and to the uterus, I am prepared to reaffirm, do not always ensue upon the total destruction of the perineum. Although, if the woman subsequently bears children, or is very fat, they are liable to ensue.

Immediate or Primary Operation.—I cannot agree with some modern gynecologists, that it is better in such cases to proceed at once to close the rent by sutures, and for several reasons, some of which have already been anticipated. The parts have suffered such a degree of stretching and contusion as to render the occurrence of inflammatory reaction, if not of sloughing, almost inevitable; the lochial discharges will make it impossible to keep the parts clean; the operation itself inflicts a severe injury when the condition of the patient is already critical from other causes; and finally, because under judicious management the rent frequently becomes partially and sufficiently closed spontaneously.

If spontaneous closure of any portion of the rent takes place under these circumstances, it is probably not usually effected by the direct contact and immediate adhesion of the lacerated surfaces. The conditions are all unfavorable to this occurrence. Lacerated and contused wounds seldom unite by first intention, and the torn edges are too narrow and irregular to be placed and maintained in exact apposition, even with the aid of sutures. The surgeon encounters sufficient difficulty in securing this result even when, at a later day and under much more favorable circumstances, and after an extensive denudation of the surfaces, he attempts the closure by the aid of sutures. It is much more probable that the union occurs in these cases by the secondary process of granulation, the cicatrization and restoration commencing at the angle of the wound where the laceration terminated, and extending thence in the direction of the vaginal orifice. This is what happens usually in the case of a lateral incision, made for the purpose of enlarging the orifice of the mouth after certain plastic operations upon the lips, and which, without great care on the part of the surgeon, is certain to defeat his operation. Indeed, I have generally found it impossible to prevent the union of the parts thus divided, except by covering one of the raw surfaces with the mucous membrane dissected from the inside of the lip.

While, therefore, the accoucheur may be advised to maintain actual contact of the raw surfaces by position, in the remote hope that some adhesion may occur, there is not in this possible chance of small results a justification for operative surgical interference. The parts should certainly not be needlessly or forcibly drawn asunder, but they may be carefully exposed to view each day, and made clean by gentle ablution; and the urine should be drawn by a flexible catheter as often as may be required for the relief of the patient, to whom nothing is more distressing than the contact of the urine with the raw surfaces of the wound.

In further support of the opinion above given, that an immediate operation is not in most cases, if ever, advisable, it must be explained more fully that, if it were possible to secure union by adhesion at this early period, the operation must be made within a few hours at most. Hewitt ("Diseases of Women," Sims, Amer. ed., vol. i., p. 462), who advises the early operation "when the rent is at all considerable," says "the primary operation should be performed within one hour from birth, while the surfaces are still raw and bleeding." . . . "It is of very little use in inserting sutures when the labor has been over some hours; union rarely then occurs." This statement is doubtless correct, and my experience in a great variety of plastic operations compels me to doubt whether the operation will be any more successful if made within an hour. The reasons for this opinion have already been assigned. But we may properly ask Mr. Hewitt what is to be done with that very considerable number of cases in which the expulsion of the placenta is delayed beyond an hour? Shall the rent be closed before it is expelled, at the risk of the sutures being torn out by its subsequent passage? Or is the accoucheur again to interfere with the course of nature, and, with more or less violence, as may become necessary, remove the placenta without reference to the present general condition of the patient or of the uterine contractions?

From any point of view it comes to this, that it is proposed to make an operation, by no means trivial in its character, requiring, according to Hewson, two or three "rather deep silver-wire sutures," not to speak of the subsequent special management of the bowels required, and the removal of the sutures; and which operation at the best is very liable to fail; and which may subsequently, in case no operation is made, be found to have been unnecessary; or which, if it becomes necessary, can be made more thoroughly and successfully at a later period—it is proposed, I say, to make the operation under every surgical disadvantage, and when the patient, prostrated and trembling from the results of a severe labor, is in the worst possible condition, both mentally and physically, to endure the shock of an operation, or even its announcement. Nothing but the most urgent, imperative necessity can justify the operation under these circumstances, and this necessity has not been shown to exist.

It is proper, also, to add that not every accoucheur is competent to make an operation of this nature, and experts in this department of surgery can seldom be obtained within the hour assigned by Hewitt as the limit of its probable success. This may not constitute an argument against the primary operation, but it may be pleasant to the accoucheur, who has omitted to perform it, to believe that happily it was not necessary or advisable.

At this early period, also, it is often difficult for an expert even to form anything like a definite opinion as to the actual extent of the lesion. A rent, which at first seems to be an inch or two in length on account of the distended condition of the perineum, will, after contraction, a few hours later, be found to be not more than a quarter or half an inch.

Secondary Operation.—In case the rent involves the perineum only, the integrity of the sphincter ani being preserved, the preparatory treatment will consist in a thorough evacuation of the bowels with a saline cathartic, administered forty-eight hours before the operation is made. On the morning of the operation the rectum should be emptied by a copious enema of warm water, to be followed by a suppository containing half a grain of morphine. The patient being then anæsthetized and placed in the usual position for lithotomy, while an assistant displaces the upper wall of the vagina with a Sims' or Bozeman's speculum, the surgeon will proceed with mouse-tooth forceps and scissors to denude the surfaces which are to be brought into contact. These surfaces should be extensive, rarely less than one inch in the antero-posterior direction, and they should extend inward along the vaginal wall nearly as far. The denudation must also be complete, the interposition of the smallest portion of the mucous or tegumentary membrane between the lips of the wound being sufficient to partially or wholly defeat the operation. All bleeding having ceased, three well waxed sutures, of the largest size of harness makers' silk, are to be introduced, the first being placed at the angle of the wound close to the sphincter. The needle, armed with a double ligature, must be inserted at a distance of from three-fourths to one inch from the margin of the wound, carried to a sufficient depth to include the entire surface which has been made raw, and brought out at a corresponding point upon the opposite side. Each suture will be introduced in the same manner. Sections of a rather large-sized flexible bougie, one inch longer than the fissure, are laid upon either side, and the double sutures drawn upon until the lips of the wound are brought together with moderate firmness, and the sutures are tied. In most cases, in order to secure accurate apposition of the margins of the wound, it is well to insert two or three very delicate superficial sutures. The knees of the patient should then be tied together lightly, with a small pillow interposed between the knees, and she may be left to repose upon her back or side, as may best suit her comfort.

The after-treatment demands the most careful attention. The bowels should be kept quiet for several days. The parts should be subjected to daily inspection and kept clean and dry. The urine should be drawn as often as may be necessary. The deep sutures may be permitted to remain six or seven days, or even longer, if they cause little or no irritation, but the fine sutures may be removed earlier. Finally, rarely sooner than after ten days, the bowels must be moved and the rectum emptied by the aid of physic, enemata, and by mechanical assistance if necessary.

In case the rent involves more or less of the recto-vaginal wall, the difficulties of the operation will be greatly increased, and it will be advisable always to paralyze the sphincter by two lateral incisions, extending backward and outward on each side, as first recommended by Baker Brown. The deep sutures must be kept in place as long as they serve a useful purpose, the evacuation of the bowels must be longer delayed, and after the sutures are removed the parts must be kept at rest and in contact until a firm union is insured.

I have made no reference to the use of the wire sutures in this operation, because, so far as the management of the perineal rent is concerned, I prefer to employ the so-called "quilled" suture, only substituting the bougie for the quill, and for the reason that I do not find the wire so easy to introduce or to remove; nor have I found it, where the perineum alone is torn, to possess advantages in any other respect. If, however, the rent or loss of structure involves any considerable portion of the recto-vaginal septum, I would recommend, so far at least as the rectal fissure is concerned, the wire suture either with or without Bozeman's clamp; but I must acknowledge that, in the treatment of this very difficult class of cases, I have had no practical experience, and cannot therefore speak authoritatively. I would prefer always to refer such cases to those who have had special practical experience in this department of surgery.

TRANSFUSION OF MILK IN OPIUM-POISONING, WITH SOME THOUGHTS ON TREATMENT.

By D. TOD GILLIAM, M.D.,

PROFESSOR OF PHYSIOLOGY AND DISEASES OF CHILDREN, STARLING MEDICAL COLLEGE, COLUMBUS, O.

Some very recent experience in the treatment of opium-poisoning, taken in connection with that acquired heretofore, suggests to my mind a question as to the propriety of much that is embraced in the conventional method of treating such cases. I refer more especially to the efforts made to combat the somnolent state and to keep the patient from sinking into insensibility. It is not the somnolence that kills, as is evident by the fact that individuals may and often do remain in a lethargic state for long periods without special detriment to the vital energies. It is further evidenced by that class of cases in which the patient recovers consciousness after the hypnotic action of the drug has expended itself, but gradually sinks and expires from the resultant exhaustion. Such cases are not uncommon. As an illustration of the ordinary course pursued in opium-poisoning, and its deleterious consequences, I will cite the following case :

Mrs. G——, aged sixty-six, was subject to excruciating neuralgia of the head. On May 23d she was suffering from one of these attacks and took, during the morning hours, several doses of chloral of about ten to fifteen grains each ; this failing to give relief, her physician, unmindful of the fact that the alternate action of morphia and chloral is specially dangerous, gave her a hypodermatic injection of morphia. He claims that the dose administered was a small one, probably not exceeding the eighth of a grain.

Very soon the patient became somnolent and a gradually-deepening narcosis apprised him of the impending danger. He tried to arouse her by shaking, shouting in her ear, pinching, pricking, flagellation, and finally by keeping her in incessant motion. Strong coffee was also administered in large quantities every few minutes, which she was goaded into taking by special efforts in the way of pinching, shaking, and the entreaties of her daughter, but which at intervals would be ejected from the stomach when that viscus became overburdened. After this had continued for some hours, I was sent for and found her in a profound stupor, with slow and quiet respiration, slow pulse, and a dry surface. The pupils were contracted to the utmost. I immediately administered atropine hypodermatically, which I repeated three successive times at intervals of twenty minutes, until a moderate amount of dilatation of the pupil was secured. In the meantime the physical tortures, the cramming of the stomach with coffee, and the enforced motion, were continued with unabated diligence, until nothing that could be done would arouse the patient, and she was carried in perfect helplessness, and with dangling limbs, to a lounge where she was supported in the sitting posture by two very energetic attendants, who continued to ply their vocation in the manner above indicated. I not only approved of all this, but urged it on with (save the expression) quiet vehemence. Cold water was now at intervals projected with violence into her face from a Davidson's syringe and a faradic battery brought into requisition, by means of which, yet for a while, voluntary movements, cringings, and groanings could be elicited. Brandy was now given hypodermatically and subsequently the intravenous injection of ammonia was practised—the latter more with a view to antagonize the chloral than the opium. During this time the respirations gradually dropped in frequency until they reached the minimum of four per minute. The pulse now ran at from 96 to 100, but varied as to force and volume, at times becoming almost imperceptible, and then again augmenting. The respirations at one period had a duplex character, in which the intervals between the deep and slow respirations were filled with very shallow, quiet, almost imperceptible respiratory movements. The coma deepened despite all efforts, and she was laid on the lounge, and the principal reliance placed in faradization, by which means the respiratory movements could be quickened for a few moments, but not maintained. The brandy and ammonia were still occasionally used and warmth applied to the surface. After a profound depression, from 1 to 3 A.M., she gradually emerged to some extent, the respirations mounting to eight per minute and the pulse improving in strength. At daylight she could be aroused so as to recognize a friend, but would immediately relapse into her lethargic state. The thermometer at this time indicated a temperature of 101.3° F. I make special note of this fact because of the prevalent belief that the temperature never rises in opium or chloral narcosis. Some years since I had a death from chloral-poisoning, following in the wake of delirium tremens, and in that case a very marked increase of temperature characterized the last moments, and continued post mortem.

At 8.30 A.M. I concluded to try the transfusion of milk. Accordingly, after making arrangements to get some milk directly from the cow, I improvised an apparatus as follows : Taking a small hard-rubber syringe, I discarded the piston, and by wrapping the nozzle of a Davidson's syringe, made it to fit air-tight into the chamber of this smaller one. I then cut down upon the radial vein, and lifting it on a button-hook, opened and introduced into it the nozzle of the small syringe, which, being secured in position by ligatures, was filled with a warm saline solution. In the meantime the milk had been obtained and kept at a temperature of 100° F. by immersion in warm water. The warm salt water with which the Davidson syringe also had previously been filled, was now displaced by milk, and the nozzle introduced into the chamber of the smaller syringe, so as to entirely exclude the air, and one pint of milk gradually thrown into the vein. The effect was striking. The respirations, which up to this time had remained at about eight per minute, promptly rose to sixteen ; being quiet, easy, full, and natural. The volume and force of the pulse increased, a general health-like suffusion or glow of the surface ensued, and the patient opened her eyes. This was soon followed by a momentary pallor, loud rattling in the throat, and vomiting ; but these unpleasant symptoms soon passed off and the patient lapsed into quietude, with an aspect so much improved as to lead us confidently to expect recovery. At this juncture, being called away, I promised to return at 1 P.M. intending to repeat the transfusion, should circumstances justify such a procedure. Unfortunately I was unable to return until nightfall, when she had just expired. She had continued in good condition until about the time of my expected call, when signs of failing became manifest, and she gradually became weaker until life became extinct.

She died of exhaustion pure and simple, and the question obtrudes itself, "How much of the exhaustion was contributed to by the severe inflictions to which she was subjected in the combat against insensibility?" Had I a case of opium-poisoning to-day, I should give less attention to the coma and more to the fostering of the vital energies. While we recognize the fact that pain is the natural antidote to opium, that exercise promotes the circulation, and that the reflex of impressions made on the skin stimulates respiration, we must not shut our eyes to the extreme probability of overdoing these things in our anxiety, of inflicting such injury and so exhausting the already overwhelmed nerve-centres, as to shut off the chances of life after the lethal effects of the drug have worn off. In the use of those means calculated to awaken the sensibilities, I should use moderation and caution, and especially would I use them intermittingly. Whatever measures are used, let them be sharp and short in duration. In exercising the patient, let there be a brisk walk or run, followed by a period of repose. In the use of cutaneous excitants, such as pinching, lashing, douching, electricity, etc., be sure that they are not kept

up too persistently, and that they are so selected and so performed as to inflict the minimum of bodily injury and yet produce the maximum of pain. Very small twigs or a broad thin paddle for whipping, a small fold of skin for pinching, quick or forcible jets of water for douching, and, above all, the use of the faradic current, are the methods and measures called for. In the use of coffee, I should be careful not to overload the stomach, as absorption is certainly not promoted thereby, and the distention of this organ only leads to pernicious reflexes and interferes with the action of the heart. I should give atropine to such an extent as to produce moderate dilatation of the pupil, would keep the surface comfortably warm, use massage upward to aid the circulation, and, lastly, if I saw the vital powers were waning, I should resort to the transfusion of milk. By this means I would expect to save that very considerable number of cases that emerge from the immediate effects of the opiate only to succumb to the exhaustion which has been so much aggravated by the cruel, and, as I now believe, irrational draft on the vital energies, in futile efforts to keep the patient awake.

NOTES ON RECENT MEDICO-LEGAL CASES.

By HENRY A. RILEY, Esq.,

NEW YORK.

Pennsylvania has followed New York in the enactment of prohibitory laws against oleomargarine, and the statute just passed takes effect from July 1, 1885. The manufacture and sale of imitation butter is forbidden after that date, and all persons having the article on hand are to be punished. The signing of the bill by Governor Pattison has caused some excitement among the commission dealers of Philadelphia, and it is not unlikely that a test case will be made on the question of the constitutionality of the law. It will be remembered that such a case was commenced in the courts of this State, and is now pending in the Court of Appeals, with the final decision remaining in great doubt. The argument is used with much force that oleomargarine, when manufactured in a cleanly manner and from pure materials, is not an unhealthy article of diet, but is rather to be preferred to the poorer grades of genuine butter, and that it is beyond the power of the Legislature to absolutely forbid the manufacture of an article which is confessedly not necessarily harmful. The power of the Legislature to enact laws more or less prohibitory on grounds of public health is one of the most important questions now before the public, and the limits of its power are not at all settled. It seems to be decided, however, that a legislature cannot validate legislation on public matters simply by saying that the public health demands such and such laws. It must in reality appear that the laws are necessary health measures, or the courts may declare them void. This was the case in a notable instance recently, where the Tenement-house Cigar Bill attempted, on alleged grounds of public health, to forbid the manufacture of cigars in certain kinds of tenement-houses; but the Court of Appeals held that the bill was on its face not a health measure, except in name, but was intended to prevent injurious competition to the large manufacturers. The law was therefore declared null and void. Somewhat the same question will come up for decision in the oleomargarine case, but the issue is more doubtful.

It is certain that there is no more interesting and important branch of law than that limiting the power of legislatures to pass laws on health questions, and the decision soon to be rendered by the Court of Appeals will no doubt help to fix the limits.

In actual fact, the law, the constitutionality of which is yet uncertain, has been so well administered under the backing of the entire farming interest, that there is almost nothing left of the manufacture of oleomargarine, and its sale has been very largely curtailed. According to the report made some months ago by the Dairy Commissioner, at least four-fifths of the traffic had been at that time destroyed, and there is probably still less now.

One of the signs of the successful enforcement of the law is the recent failure of the Commercial Manufacturing Co. of this city, once the largest manufacturer of oleomargarine in the country, and having a nominal capital of $10,000,000. The company is now in the hands of a receiver and has not done any business for a considerable time.

Two recent suits in this city will have some interest for physicians; one of these was a suit brought by the executors of the late Dr. J. Marion Sims against the United States Trust Company to recover $5,000, alleged to have been improperly paid on a check by the Trust Company. Dr. Sims, when in Europe in 1882, made Gilbert L. Crowell his trustee, and money deposited in the Trust Company was drawn out by him and he became a defaulter. Dr. Sims claimed that the Trust Company had no legal notice of the holding of a power of attorney by Mr. Crowell, and that it should not have paid the money on his personal check. The case has been twice tried, and now for the second time the estate of Dr. Sims has been successful in establishing its claim. The other suit is that of Dr. James M. Schley for medical services. The defendant, Mr. Arthur Bloodgood, had the disease called locomotor ataxia, and the action hinged largely upon the question whether the disease was curable, and whether the so-called Salisbury diet, invented by Dr. Salisbury of this city, is approved by medical authorities.

Quite a number of physicians were examined on the trial, and the jury rendered a verdict in favor of Dr. Schley.

The firm of J. C. Ayer & Co., patent medicine manufacturers of Lowell, Mass., are in trouble, the custom authorities of Canada having seized at Montreal a large quantity of medicines, valued at $150,000. The charge is made that there has been a serious undervaluation practised for ten or fifteen years in goods sent to Canada, and that a loss of revenue amounting to $25,000 a year has been suffered by the Canadian Government. The firm deny the charges, and say that the medicines sent were not compounded, and, being forwarded in bulk, were valued at cost, and that this was proper under the circumstances.

The charges made by Dr. Robert A. Gunn, that a bribe was solicited by Senator Coggeshall for a favorable report upon the bill to incorporate the "College of Medicine and Surgery," have not been either proved or disproved as yet. Dr. Gunn gives his version of the matter with considerable particularity, but Senator Coggeshall thus far contents himself with a simple denial. This answer is certainly not sufficient, and a rigid investigation should be had into the matter. If this is not done in the courts by a suit for libel, it will no doubt be secured by a legislative inquiry when the Legislature assembles next winter.

The charge of bribery does not affect, however, the merits of the bill, and these do not appear very clearly. There are now eight medical colleges in this city giving the degree of M.D., and there is certainly no such need of another as to warrant a special law of incorporation, when the general law of 1853 is broad enough to cover all attempts to establish new colleges. There will be no opposition to Dr. Gunn if he should create a new medical school under the law, but the reason for special legislation does not appear.

A prominent physician in a neighboring city received the following note from a lady a few days since: "Dear Doctor: Please come to see my brother at once, and bring your urethra with you. Respectfully, Mrs. ——." The doctor answered the call, and carried a catheter.—*Atlanta Medical and Surgical Journal.*

PULSATING PROPTOSIS AND ELASTIC TUMOR OF LEFT ORBIT,

Consequent upon a Trauma of the Skull—Ligation of Left Common Carotid.

By ROBERT SATTLER, M.D.,

Ophthalmic Surgeon to the Cincinnati Hospital, Cincinnati, O.

(Continued from page 656.)

In this review of the pathological evidence in support of rupture of the internal carotid, etc., it is interesting to note the strongly corroborative proof offered by the clinical histories of many of the fatal and successful traumatic cases. From the preceding analysis of the anatomical alterations the clinical characters of this lesion are readily deducible. I include in this brief review of the clinical features only the traumatic cases on record. The symptoms follow in the order of prominence and frequency, as illustrated by the published cases and the special prominent features existing in the case which forms the subject of this article.

A. Mound-like elevation of the palpebral area invading also the temporal, nasal, and frontal regions, associated with the following symptoms:

1, Increase in the thickness of the lid, due to vascular engorgement; 2, reduction of the muscular excursion of the upper lid; 3, dusky, cyanotic appearance of the skin; 4, tortuosity and distention of the cutaneous and subcutaneous veins; 5, prominent tortuosity of terminal cutaneous veins, notably the branches accompanying the ramifications of the naso-ciliary and angular arteries; 6, palpation may discover a feeble pulsation and the characteristic purr or thrill in these veins; 7, injection of the ocular and palpebral conjunctiva; 8, chemosis—particularly where the obstruction to the return of the venous blood is sudden is this symptom one of prominence and importance; 9, disturbance of the muscular apparatus of the iris, sluggish pupillary movement, myosis, mydriasis; 10, interference with the intra-ocular circulation, resulting in congestion of the choroid, œdema of the retina, pulsation and distention of the retinal veins, papillitis, neuro-retinitis, etc., with their resulting complete or partial suspension of function of the eye; 11, paresis or paralysis of the motor and sensory nerves of the eye and its surroundings; 12, various other symptoms referable to the affected orbital area not necessarily consequent upon it, but directly resulting from the primary or causative lesion, fracture of the basis cranii.

B. Pulsating elastic tumors or prominences in the anterior portion of the orbit, varying in number, shape, dimension, and locality.

1, The upper and inner portion of the orbital opening, between the globe and the bony margin of the orbit, the most frequent locality—they may also be situated above or outward and downward; 2, these "bossy protuberances" often pulsate visibly, in others a simple stretching of the overlying skin is necessary to render them so; 3, palpation discovers a more or less forcible impulse; 4, pressure with the finger against these elastic tumors involutes the glove-finger like apex, but does not arrest the pulsation; 5, arrest of pulsation can only be accomplished by compression of the common carotid, but even this in some cases only results in a temporary cessation, which after some time gives way to a feeble pulsation; ligation controls it more thoroughly, but it also may fail to arrest it, and other measures—galvano-puncture, injection of irritants, and ligation of opposite carotid—may prove necessary.

C. Proptosis or displacement and pulsation of the globe. In many cases the protruded eyeball is the seat of distinct rhythmical pulsations. If it is not visible it can be readily discovered on palpation.

1. The impulse, on palpation, is generally strong; 2, the firmest pressure against the closed lids and globe does not arrest it; 3, compression of the carotid at once controls it; in some cases it is only a temporary control and compression of the opposite carotid is necessary to effect a complete cessation. This also applies to ligation; 4, it is probable that the heavy upper lid exerts a controlling or compensatory pressure against the globe and guards against *excessive prominence.*

In the present case this was illustrated. When the palpebral fissure was opened with the thumb and index-finger, the pulsating globe advanced at once into the lid-opening and became so prominent, that it could be easily strangulated by the lids.

D. Subjective symptoms.

1, Discomfort, feeling of fulness, pain, resulting from the prominent globe and vascular engorgement of palpebral area; 2, disturbances of vision, either in consequence of the pendent lid or paresis or paralysis of the levator palpebræ superioris; 3, diplopia, due to paresis or paralysis of the extrinsic muscles; 4, defects of vision from disturbance of the retinal and choroidal circulation, etc., paralysis of accommodation; 5, existence of noises in the head, referred to the affected orbit and also to different and remote parts of the head; 6, these sounds vary in loudness, intensity of impulse, pitch and duration. Rarely does the patient speak of one sound, but in most instances refers to several. He may designate one as the principal or loudest sound and characterize it as beating, throbbing, or blowing, and compare it with the noise made by the escape-pipe of an engine (a most frequent comparison), and similar characteristics may be assigned to the other sounds. Particularly does the mewing, cooing, or moaning attribute of one sound, called by the French the bruit de piaulement or miaulement deserve mention. In the present case it had a moaning or distant vibratory cooing sound, and corresponded to the third orbit.

E. Corroborative proofs offered by the analytic interpretation of the subjective phenomena, aided by test of vision and functional examination of the eye and physical examination of the head and orbit.

1. Palpation detects increase or decrease of the orbital tension. In most cases the orbital tension is increased; position of the head and posture of body influence it; digital compression of the carotid increases it markedly. In the present case the orbital tension was pronounced in the standing, greater in the recumbent position, and greatly increased when the carotid was compressed. 2. It also discloses the force of impulse and its rhythm and duration in the pulsating tumors and eyeball. 3. Auscultation analyzes the special characteristics of the sounds and localizes their intensity, etc.

I report the following case because it offers, in my opinion, satisfactory clinical evidence for the existence of this lesion, upheld by the preceding pathological and clinical analysis and first accurately described by Dr. Delens; the latter's views, supported by Mr. Rivington in an excellent paper, and fortified and enlarged by the addition of a most careful compilation and deductive reasoning, based upon all cases on record, by Professor H. Sattler.

It is, of course, admitted that clinical evidence can only be considered corroborative; upon it alone a diagnosis of a lesion, particularly one with such an obscurity of origin, cannot be upheld. It therefore can only be considered problematic; yet the more thoroughly the clinical phenomena of a case are found to correspond with and resemble those existing in the isolated fatal cases in which post-mortem examination was possible, can they be regarded with greater probability as constituting the manifest and correlated phenomena of this pathological lesion.

About two years ago, G. P——, aged eighteen, a coal-miner, while at work in a coal-shaft, sustained a serious injury of the head. It was caught and crushed between two loaded cars. He was found and removed in an unconscious condition, bleeding profusely from both ears and nose. In about three days he regained consciousness, replied to questions, and at once remarked that his sight and hearing were defective. He also complained

of great prostration and impairment of sensation in the extremities, but no paralytic symptoms existed, and his intellect was unimpaired.

The sanguinolent discharge from the ears continued about five days, then ceased in the left and changed to a purulent discharge in the right ear; this continued for five or six weeks and was attended by marked deafness.

No marked contusion or ecchymosis of the scalp or face existed immediately after the accident.

On the ninth day he had so far recovered that he was able to walk about. His chief complaint at this time was defective vision, diplopia, vertigo, and deafness. The deafness was so pronounced that he could not understand very loud conversation.

These symptoms lasted about five weeks and were followed by gradual improvement of hearing and vision, but vertigo, tinnitus, and peculiar humming sounds in the head continued and at times were greatly increased.

At this time, five weeks after the accident, he determined to seek the advice of a physician in Richmond, Va., to obtain, if possible, relief from the diplopia, deafness, and noises in the head. He is confident that at this time no perceptible prominence of the eye existed, but he distinctly mentions a peculiar interrupted cooing or beating sound which he could not localize, but which differed from the continuous ringing sound referable to his ears, notably the right one. Two months after the accident he noticed, but whether sudden or gradual, or whether accompanied by a sudden noise or snapping sound in the head he cannot remember, a fulness of the left palpebral area and protrusion of the globe, together with a pulsating or throbbing sensation in the orbit. The sight of the left eye at this time was more impaired.

In the course of several weeks the noises in the head increased in intensity and assumed distinct characteristics, so that he was able to distinguish three distinct sounds.

The first and loudest was the bruit, which another person could hear by placing the ear over the closed lids of the left eye, or over the left temporal region; it was loudest and resembled the exhaust of a steamboat; the second, next loudest, was something like the first, but much weaker and of higher pitch; this was followed by the third sound, which he compares to the sound made by a wagon, loaded with iron, passing down the street. This third sound was cut short by the first sound beginning again.

By placing his finger over the closed eyelids, he could feel the pulsation of the globe; he could also, by pressure, cause the prominent eye to recede a little.

The protrusion of the globe continued to increase, and, in addition, a livid appearance of the palpebral area, together with a tortuous and distended appearance of the superficial veins of the globe and eyelids, developed. The noises in the head and the discomfort and vertigo attending all prolonged physical exertion forced him to abandon his work, and he determined to seek the advice of Dr. E. Williams, of this city.

Stat. præs.—Strong and muscular young man; no irregularity, prominence, or depression of head; the entire left palpebral area is the seat of an elastic swelling which extends and invades also the frontal and temporal regions; the skin is livid and discolored; numerous large and small veins traverse this entire swelling; near the inner canthus the distention and tortuosity is greatest; several large varicose veins extend across the superciliary and nasal regions to the opposite side. Placing the finger over these distended vessels, a distinct thrill or purr is felt. Stretching the skin toward the temporal side, a distinct pulsation occupying the inner and upper portion of the orbital opening is seen; if rendered more tense, pulsation of the globe is also observed. On palpation a most forcible impulse is communicated to the finger, and a fusiform or glove-finger-like elastic projection is discovered immediately underneath the inner and upper orbital margin. Pressure against this smooth and elastic projection involutes the flattened apex, but does not arrest the pulsation. Compression of the common carotid at once arrests it.

The upper lid droops and the palpebral fissure is smaller. The action of the levator is not, however, suspended, but only interfered with by the increase in the thickness of the lid and contents of the orbit.

The ocular and palpebral conjunctiva are traversed by numerous large and tortuous veins. The cornea is clear, iris brilliant, pupil dilated and sluggish. V. = 0.4.

Ophthalmoscopic examination.—Media clear; intense congestion of disk, and tortuosity and distention of retinal veins. The disk and adjoining retinal regions present an intensely livid and œdematous appearance. Pulsation of the veins exists and is rendered more forcible by slight pressure against the globe.

No pathological alterations of the fundus oculi, however, are discoverable.

On opening the lids with thumb and index-finger, the globe at once advances into the palpebral fissure and distinct rhythmical impulse or pulsation is seen and felt.

Proptosis, or an advance of the globe forward, downward, and a little inward, of about three-fourths of an inch exists.

Pressure against the closed lids encounters a forcible pulsation of the globe and also of the elastic projection inward, but the pulsation cannot be arrested; it does, however, effect a slight recession of the prominent eyeball. It is so painful that it cannot be long endured. Compression of the carotid at once arrests the pulsation of the eye and also of the elastic projection; it also permits a more complete reduction of the proptosis.

Complete paralysis of the abducens exists in both eyes. The secondary contraction of the internus is very pronounced, particularly in the left eye. Here the contraction is so marked, and the displaced globe is so markedly rotated around a vertical axis, that the equator almost presents and corresponds with the vertical meridian of the orbital opening. The excursions of the other muscles of the left eye are restricted but not inhibited; most marked is this of the superior rectus.

Auscultation over the closed lids, temporal, frontal, or parietal region, at once discovers several bruits.

The loudest is a forcible blowing sound synchronous with the heart's systole; it is followed by a similar sound, more prolonged, of higher pitch, and of less force; this merges into the third, a peculiar piping, at times vibratory sound, which is cut short by the first again beginning. These sounds have their intensity over the left orbital opening, brow, and temporal region, but can be heard over the parietal and occipital bones on both sides of the head.

Compression of the common carotid temporarily arrests all three sounds. After some time, however, the first sound reappears, very faint, and has the piping characteristic of the third sound; the second and third, however, do not return. By firm compression of the distended vessels traversing the left side of the nose and inner canthus this partial return of the first sound can be arrested; more effectually, however, is this accomplished by compression of the right common carotid.

These noises are all influenced by mental excitement and physical exertion.

With the exception of the ears, which both show the evidence of suppurative inflammation of the middle ear, retraction, opacity, cicatricial alterations, etc., and a small perforation of the right membrana tympani, the probable consequences of a rupture of the membrana tympani, etc., or fracture at the base, no other symptoms indicative of fracture of the cranium or injury to the cerebro-spinal system exist.

To test the influence of rest and arterial sedatives, the patient was kept quiet and veratrum viride, aconite, digitalis, etc., administered in increasing doses. No perceptible influence, however, was exerted on the orbital lesion.

Digital compression, kept up by relays of students, was next tried; this was so painful and became so unbearable that instrumental compression was substituted. Digital compression was kept up about fourteen hours, followed by instrumental compression for about eight hours.

The patient then complained of vertigo and became very pale, and the ear became very cold.

This was followed again by arterial sedatives, compression of the facial and branches of the naso-ciliary arteries but no change or modification of the symptoms was brought about.[36]

The inefficacy of these measures thoroughly established, ligation of the carotid was determined upon and approved of by Dr. E. Williams and Dr. L. C. Ayres. The case was then submitted for consultation to my friends, Drs. P. S. Conner. Thomas Kearney, and N. P. Danbridge, who all three pronounced in favor of ligation.

On January 12, 1884, I ligated the left common carotid, above the omo-hyoid muscle, without mishap or complication.

The following are brief extracts from the copious notes made by C. R. Holmes concerning the progress of the case during and after the operation:

"Took ether well; pulse full and strong; vomited several times during first part of operation. Anterior jugular was enlarged and crossed obliquely the superior carotid triangle.

"The sheath was reached and the ligature needle, bearing a double No. 2 McFarlan & Co. catgut, prepared according to Lister, was passed without much difficulty around the artery, and tied and cut off short.

"It was used double, because no heavier gut could be procured in time for the operation. The deep fascia were brought together by means of two catgut sutures, and six to close the wound of the superficial structures. During the first hour following the operation he vomited five or six times.

"Twenty minutes after the operation the proptosis and fulness of the palpebral area had greatly diminished; with the diminution of the prominence there was also complete disappearance of all noises and pulsation. This was noticed as an immediate result following the tightening of the ligature.

"At 10 P.M.: Pulse, 120; temperature, 99⅘°. Gave one-fourth grain morphia hypodermically. At 3 A.M. the morphia was repeated on account of pain in the wound. Faint bruit reappeared, but no pulsation.

"January 13th.—Pulse, 132; temperature, 102°. Gave tinct. aconite, gtt. ij., tinct. belladonnæ, gtt. v., every four hours.

"Proptosis diminishing; no pulsation; bruit unmistakably heard. It is altered in pitch and character and is not always audible to the patient. It is reduced in intensity and quality and resembles more a cooing sound. The engorged and tortuous palpebral veins have disappeared. Proptosis much less; left cornea about on a level with right one. Difference in temperature between the two sides of the face less marked to-day; the left is, however, perceptibly cooler. Face has lost extreme pallor which existed for hours after the operation. Frequent paroxysms of perspiration on brow and nasal region of left side. Wound doing well.

"January 14th.—Very restless during the night. Pulse fluctuating between 106 and 110; temperature, 101⅘° and 102. Gave morphia hypodermically, gr. ¼, twice during the night and continued aconite, etc.

"Knuckle-like prominence less pointed; orbital tension altered; more and greater resistance on palpation.

"Bruit about same. Mind clear. Some swelling about wound and slight discharge.

"January 15th and 16th.—The bruit has diminished; orbital tension remains increased. Diffused redness and swelling about wound extending into clavicular regions; simple iodoform dressing continued.

"January 17th.—Slight return of pulsation, but the same distant, almost continuous cooing character of bruit continues. Position influences the pulsation; lying on the left side increases it.

"A slight purr or crepitation feeling is also discovered on applying the finger to the veins on the left side of the nasal region; pressure, however, over inner region of inner canthus or median line of brow causes it to disappear; it also brings about, not immediately, but after about three minutes of continued pressure, a cessation of the bruit. Had headache for several hours on left side. Pulse, 96; temperature, 99½°; respiration, 20.

"January 18th.—Wound discharging, but no unfavorable local alterations. Patient says that he has heard the noise less to-day than at any time since the operation. The pulsation continues, but is very feeble. The fulness of the palpebral area is perhaps a little more pronounced; the proptosis, however, is not.

"January 19th.—Was permitted to sit up. No vertigo and absence of all unfavorable symptoms."

Five weeks after the operation the patient was discharged. At this time the following points were noted: Almost complete reduction of the proptosis. Inability to produce pulsation of the globe. Marked improvement of sight, V= 0.9 with −0.75 ph. Diminution of the distressing noises and absence of the feeling of distention and discomfort about the orbit.

Perceptible fulness of the palpebral area, and a feeble pulsation of the elastic tumor, which is altered in shape and reduced in size, still exists. On auscultation, over the closed lids, a bruit, resembling a distant cooing sound, is heard; it is a prolonged sound gradually increasing and diminishing in intensity, and is not associated with other sounds. The patient states that he hears but one sound, which resembles a cooing in the distance; it is influenced by position and is greatest in the recumbent posture.

Pressure at the inner and upper portion of the roof of the orbit arrests, not immediately, but after several minutes of firm pressure, the pulsation of the elastic tumor, and also reduces the intensity of the bruit. It cannot, however, be made to disappear entirely by pressure in this locality. Compression of the right carotid at once arrests pulsation of the tumor and also the bruit.

The wound did not heal throughout by first intention; a mild suppurative process involving lower portion was set up.

The short catgut ligature resorted to by Lister, Maunder, and other surgeons was employed. I was prompted to resort to it in this case, however, more particularly from personal observation of Dr. E. Gruening's successful case,[37] assisting him at the operation, and witnessing the immediate and remote results. This case deserves a most careful perusal, as many of its clinical features were phenomenal. It was a brilliant achievement of diagnosis, but even more conspicuous for the immediate, complete, and lasting success of the surgical interference proposed and instituted by Dr. Gruening.

May 27, 1884.—Patient returned, willing to submit to further treatment, if so advised. The proptosis had remained reduced, the elastic tumor pulsated, but not forcibly; the fulness of the lid-area was perhaps a little more pronounced, but the cutaneous surface did not present that dusky cyanotic appearance, although the superficial veins near the inner canthus were still prominent and tortuous. A thrill or purr in these prominent vessels could not be discovered.

[36] Several days preceding the operation I made a physical examination of the chest, with special reference to the heart-sounds. Marked pulsation of the external jugular veins and also of all the superficial veins of the neck on both sides existed. In addition a forcible pulsation over the sterno-clavicular notch and a widely diffused pulsation over the second intercostal space on the left side was also noticed, and on auscultation a systolic bruit, with its intensity over the pulmonary orifice, was discovered. An intrathoracic aneurism was suspected, and Drs. J. C. Mackenzie and Keyt were asked to make a more thorough examination. This was kindly done and the careful and accurate sphygmographic tracings taken by Dr. Keyt did not uphold the existence of intrathoracic aneurism; the latter looked upon the existing physical signs as the manifestations of a congenital anomaly of the right side of the heart. To both gentlemen I am indebted for their careful examination, which greatly modified my fears as to the final outcome of the proposed operative interference.

[37] Gruening, E.: Archives of Ophthalmology and Otology, 1875.

The patient stated that he had resumed his work in the coal-shaft and had succeeded fairly well. He had not experienced the discomfort and pain which invariably developed, after even moderate physical exertion, before the operation. In referring to the distressing noises, he mentioned that the "exhaust sound" had entirely disappeared; the sound of "iron rattling" was only heard now and then, when up and about, but was always present and distinctly heard whenever he lies down. The cooing sound has grown less and less; to-day, although he has travelled several hundred miles and is exhausted, he has not heard it constantly. On auscultation, the same piping-cooing sound is heard, and at times presents a vibratory characteristic. It is probable that the patient does not hear two distinct sounds, but it is simply an alteration in the pitch, intensity, and rhythm of one sound, which is influenced and modified by position of the body.

The sight of the left eye is normal, with —0.75 Sph., and is better than that of the right. Under these circumstances, I did not consider further surgical treatment justifiable or specially indicated, and although the patient had come with the intention to have the right carotid ligated or to have the elastic tumor injected with an irritant solution, or have galvano-puncture resorted to, further interference, so long as the existing favorable conditions remained, was advised against.

Clinical Department.

THE BEST METHOD OF USING THE LONG SIDE-SPLINT.

Dr. M. A. Veeder, of Lyons, N. Y., writes to call attention to some modifications in the application of the long splint in fractures of the thigh. He makes extension in the usual manner by means of adhesive plaster, extending a little above the knee, the cord, with weight attached, passing over a pulley at the foot of the bed: "The long side-splint should extend from within three inches of the axilla to about the same distance below the sole of the foot. It should be light and somewhat elastic, being not more than half an inch in thickness, or less if of hard wood, and being about four inches in width. It should be upholstered smoothly with curled hair. This can readily be done at any cabinetmaker's shop, at small expense. The upholsterer should be directed not to draw the muslin cloth, covering the hair, too tightly. The splint, having been properly prepared, and extension being made upon the limb as described, the final adjustment is to be made as follows: A single strip of cloth, long enough to reach from the perineum to the ankle, and wide enough to encircle both the limb and the splint, is to be drawn smoothly beneath the limb. The outer edge of this cloth is then to be drawn upward against the exposed face of the splint, and made fast along its upper margin, by means of a row of safety-pins, while the splint is held snugly in position alongside the limb. The inner edge of the bandage cloth is then to be drawn firmly inward and then upward, so as to surround the limb smoothly, being likewise fastened along the upper margin of the splint by means of another row of safety-pins. The same manœuvre is repeated with another broad bandage, extending from the hips to the axilla, and long enough to encircle the body and the splint. By loosening or tightening a safety-pin here and there the patient can be held very firmly and without undue pressure upon bony prominences. The bandage cloth used need not be more than one thickness and is best applied next the skin. In case that bedsores have formed, the bandages may be tightened so as to be very firm, and the weights removed temporarily while the patient is turned upon the side for rest and treatment."

Signs of War.—Our Russian exchanges give evidences of increased activity in army medical circles. A new society of military surgeons has just been established at Moscow.

Progress of Medical Science.

Acute Myelitis in the Cervical Region.—Dr. Moel relates the case of a lady, fifty years of age, who suddenly experienced a rigidity of the fingers, and soon after found that she could neither walk nor stand. The fingers could not be fully extended or flexed, but the arms were otherwise normal. The right leg had some power, but the left was paralyzed. At the end of two days there was complete paralysis of both legs, with abolition of the patellar tendon reflex. Paresis of the upper extremities occurred a little later, and on the eleventh day of the attack the patient died. At the autopsy a lesion of the anterior horns was found extending from just above the point of exit of the fifth cervical nerve to the lower end of the cervical cord. The gray substance was irregularly mottled, but the ganglion cells and nerve-fibres were intact. In the lateral and posterior columns were many spots which were not colored by hæmatoxylin, and there were also here and there few granular cells.—*Gazzetta Medica Italiania Lombardia*, May 9, 1885.

Capsicum in the Treatment of Anal Fissures.—In a recently published thesis Dr. Panzat has recorded a number of cases of fissure of the anus treated by the internal administration of capsicum. The remedy was given in doses of three grains morning and night. In most of the cases a cure resulted within a comparatively short period of time. The cases recorded were too few in number to serve as a basis for any definite conclusions; but the remedy being so simple and the effects in certain cases so beneficial, the author concludes that a trial of it should always be made, and if at the end of a few days no improvement occurs, recourse may be had to forcible dilatation.—*Raccoglitore Medico*, April 10, 1885.

Muscular Atrophy Consecutive to Pleurisy.—At a recent meeting of the Hospitals Medical Society, M. Desplats read a paper in which he stated that he had noted a rapid atrophy of the muscles of the thorax and shoulder upon the affected side in cases of pleurisy. He regarded it as a phenomenon similar to the muscular atrophy occurring with joint disease. In one case he observed well-marked atrophy within ten days after the commencement of the pleuritic attack. The evil consequences which may result from this atrophy are permanent deformity of the thorax, lateral curvature of the spine, and an impairment of the respiratory function, possibly favoring the development of tuberculosis. The treatment proposed by M. Desplats consists in an early evacuation of the effused fluid, faradization of the muscles of the thorax, vocal gymnastics, and the inhalation of compressed air.—*Le Concours Médical*, April 18, 1885.

Reflex Paralysis of Uterine Origin.—Dr. Gomez Torrez relates the case of a woman who had suffered for several months from progressive paralysis and atrophy of the upper extremities. Various plans of treatment had been proposed and tried without success. The woman was found to have a parenchymatous metritis with ulceration of the cervix. Treatment was then directed to this condition, and was speedily followed by a return of the power of motion and a disappearance of the muscular atrophy.—*Annales de la Société de Médicine de Gand*, March, 1885.

Diagnosis of Obscure Cases of Nephritis.—Dr. J. Wolff states that after the administration of thirty grains of iodide of potassium, in a healthy man the greater part is excreted with the urine; but if the kidneys are diseased the excretion occurs almost entirely through the salivary glands. He thinks that this fact may be made use of in the diagnosis of obscure forms of renal disease.—*Rivista Clinica*, No. 3, 1885.

Atrophy of the Region of Rolando in Relation to Delayed Power of Locomotion in Children.—Dr. Voisin (*Rivista Clinica*, No. 3, 1885) records the results of several autopsies in children who were very late in beginning to walk, from a study of which he concludes that this phenomenon is always associated with an atrophy, more or less complete, of the cortex at the upper and internal part of the frontal and ascending parietal convolutions, near the paracental lobule. Certain other cerebral symptoms are usually associated with late walking, such as slowness in learning to talk, awkwardness in using the arms, difficulty or impossibility of learning to write, incontinence of urine, vices of conformation and asymmetry of the ears, etc.

Mercurial Poisoning at the Mines of Almaden.—According to Raymond, "Almaden is a village of seven thousand inhabitants, most of whom are employed at the mines. These consist of three principal shafts of an average depth of three hundred metres, in which the ventilation is difficult and imperfect. The mercury is found in the form of the sulphide, and in the liquid state as the result of decomposition of the cinnabar. Other work-people come from the neighboring villages during the winter to help in preparing the metal. They work at the furnaces, and assist in the sublimation, so that they are fully exposed to the poisonous vapors, but they are rarely affected, as at the end of their short spells of three hours they return home. If some of them are attacked by salivation, probably the result of individual predisposition, which plays an important part in mercurial poisoning, they soon recover, thanks to the good air and the activity of their lives, for nearly all are cultivators. Of the miners who live in Almaden the majority are not affected at all, or only to the extent of a slight stomatitis. Those who suffer more severely are persons with a predisposition, and those who stay longer in the mines than the rules enjoin. Six hours is the length of each spell, but this is often exceeded from the desire for gain. Those also suffer who indulge in excess of alcohol, or who come into the mine sweating profusely. The workmen who employ their spare time in agriculture are rarely affected, and when they are they recover rapidly by staying away from the mine. Some of the workmen in the mine suffer from stomatitis; even the engineers themselves sometimes are attacked by salivation, with dryness and heat of the mouth, accidents which yield rapidly to chlorate of potash. The workmen rarely use any treatment for themselves, and salivation is followed by swelling of the mucous membrane of the mouth, fetid breath, ulceration of the gums and lips, and finally loss of the teeth. Some are not attacked by gingivitis but only suffer discomfort in the mouth; others are affected by salivation only. All these people continue to work until abundant salivation or serious constitutional symptoms drive them to the hospital. These accidents are less frequent than formerly, owing to better regulations. Sometimes symptoms of more severe poisoning come on rapidly, but, as a rule, they are slow. The tremor commences by a sense of weakness in the limbs, by pricking or pain in the muscles; it affects the upper extremities first, and may be restricted to them, especially if treatment is commenced at once. It may extend to the lower extremities, to the lips, the tongue, the orbiculares, the eyelids, and the zygomatici. During repose or sleep the tremor is absent, but as in insular sclerosis it increases under the influence of voluntary movement, exertion, or after fatigue or alcoholic excesses. The tremor may be so great that the patient cannot walk. Convulsions and contractions may be present, the flexor muscles being affected in the latter case. Violent muscular pains sometimes occur. The tremor may be localized in certain groups of muscles; thus, it was noted in one case in the intercostals, in another in the diaphragm. The muscular walls of the viscera appear to be exempt. Paralyses are rare, but still do occur, especially in the lower limbs. The cachexia begins by general weakness, pain in the back, malaise, and headache; the appetite disappears, the tongue is white, and there is an unpleasant taste in the mouth; the patient is depressed and silent; his complexion is dull, or yellowish; he wastes rapidly. Most cases, under suitable treatment, rapidly recover, retaining only their sallow looks, and some degree of anæmia. In advanced cases, now happily rare, the patient loses all power of motion. These sufferers are very susceptible to the influence of cold. Neuralgias, vertigo, hallucinations, insomnia, epilepsy, amaurosis, albuminuria, ulcerated throat, diseased liver, conjunctivitis, and bone diseases have not been observed in any case. Among skin diseases, pellagra only has been noticed, especially in those addicted to alcoholic excesses. As syphilitic patients are not admitted into this hospital, no observations could be made on the influence of the intoxication on the course of this disease. The people in the neighborhood who do not work in the mines do not suffer at all from the metal. For treatment it is usual to employ a mouth lotion composed of tincture of cochlearia, hydrochloric acid, sulphuric acid, and honey; it gives very good results. Chlorate of potash is also given. For the tremor many remedies have been tried. Iodide of potassium has disappointed the expectations entertained of it. At present bromide of potassium is used, but the best results are obtained from faradism. Under its use the tremor disappears, the pains are allayed, and the patient feels so much relieved that he usually begs for this treatment. Iron, quinine, and wine, with good nourishing food, form an important part of the treatment. Good air and diaphoretics are also precious aids to the cure."—*Birmingham Medical Review*, April, 1885.

The Early Diagnosis of Typhoid Fever.—Dr. Hardy calls attention to the following symptoms which he regards as in a certain sense characteristic of typhoid fever in the earliest stages (*L'Union Médicale*, No. 6, 1885): There is cephalalgia, most often frontal, but sometimes occipital, and radiating into the neck, which may be somewhat stiff. The patient lies habitually on the back, and seldom moves. The face is somewhat pale, the countenance without expression, in general serious and grave, and a smile is seldom provoked. When the person is addressed directly he answers briefly and in monosyllables, although the intelligence is at this period usually unimpaired. There may be a little delirium at night, and insomnia is very constant. The tongue is red at the edges and at the tip, but whitish on the dorsal surface. The spleen is increased in volume. Diarrhœa, when present, is accompanied with iliac gurgling. The temperature is elevated, but the pulse is not very frequent, is full and resisting, and sometimes dichrotic, though this is of less common occurrence than is generally supposed. The urine is usually diminished in quantity. The so-called *tache cérébrale* is readily produced, but of more importance, as more especially diagnostic of typhoid fever, is the *corde musculaire*. If the biceps muscle be pinched between the thumb and index-finger and snapped, like a guitar string, a circumscribed contraction will occur at that point with the formation of a hard, tense swelling, which disappears after a brief period. If the patient, in whom no well-defined local trouble can be discovered, presents all the above-described symptoms, the diagnosis of typhoid fever can, Dr. Hardy claims, be made with almost absolute certainty.

Heredity in Bright's Disease.—Dr. Baudet published, some time ago, a study of three cases of nephritis, occurring in the same family, from which he was led to the belief that the disease might, in certain cases, be hereditary. This hypothesis has received a measure of confirmation from another series of cases published by Dr. Kidd. The latter related to a woman, sixty years of age, for many years a sufferer from Bright's disease, of whose twelve children seven died of the same malady.—*Annales de la Société de Médecine d'Anvers*, March, 1885.

Puerperal Peptonuria.—Peptonuria is a constant phenomenon in the normal condition of things after childbirth. It begins mostly on the second half of the first day, continues without interruption to the fourth day, frequently to the seventh, becomes gradually slighter, and vanishes entirely after the twelfth day. Peptonuria occurs both in primiparæ and multiparæ, in suckling and in non-suckling women, after labors at full term and after premature confinements. It is found also in solitary pathological cases. From the results of Fischel's experiments it follows that the urine contains peptones during the period of involution, and, in fact, at a time before fatty degeneration of the uterus has commenced. Whether, however, both the simultaneous appearances, the commencing involution of the uterus and the peptonuria, stand in causal relation the one to the other, is not clearly established by the facts adduced. All experience of pathological peptonuria until now points to the fact that it occurs when leucocytes containing peptone are decomposed, which being thus set free reaches the blood. The nearest analogy to this in puerperal peptonuria is the changes in the inner surface of the uterus, and the advent of the lochia. The lochial secretion, chiefly composed of blood on the first and second days, assumes a purulent slimy condition through abundant intermixture of leucocytes, and on this account the existence of peptones in it may be inferred. From experiments on ten women, conducted over a period of eleven days, Fischel concludes that the lochia frequently contain peptone. But peptone in the urine and peptone in the lochia are not even transiently connected. The urine contains it when the lochial discharge is free from it, and in fact can contain none of it, judging from its bloody condition in the first few days after labor. Conversely, peptone was found in the lochia when the urine was free from it. Fischel thinks he is warranted in asserting that it is at least very probable that the peptone in the urine does not proceed from the lochia. This assumption is strengthened by the circumstance that the conditions for reabsorption of peptone from the lochia are certainly more unfavorable than in the case of a circumscribed abscess. In such a case peptone is reabsorbed if the pus-cells are disintegrated in the stagnated fluid, whereas the lochia have free outlet. The next point to consider is whether in the lying-in state there does not occur an accumulation and partial degeneration of leucocytes in the inner and muscular layers of the uterus, which may be assigned as the cause of the peptonuria. It is not likely, for however rich these layers may be in migratory cells, the number of these is insignificant when compared with those, say in an inflamed lung. In the latter case, too, the fate of the migratory cells is true disintegration, whereas, in the normal puerperal uterus they fulfil regenerative functions and contribute to the reconstruction of the organ. Whence, then, is the origin of the peptone? Direct experiments were made to ascertain whether the muscular substance of the uterus in the course of its involution gave rise to peptone. Fischel had seven opportunities for testing both muscular and mucous layers for peptone. The method is given with precautions for eliminating error. He concludes that the puerperal uterus contains peptone in its muscular substance. Analyses were also made of quite fresh preparations of the uterus in women and in animals, which established that its presence is connected with regressive changes in muscular tissue. He infers that peptone is often present in the fresh tissue of the uterus, and that its origin during life is securely established. How it is formed in the uterus is not so clear. One thing is plain from all the cases, that when the uterus is at perfect rest there is no peptone to be found in it. Thus it is not to be found in the unimpregnated uterus, nor long after the uterus has evacuated its contents. The place where the peptone is chiefly found is the muscular tissues. The mucous membrane only contains it in exceptional cases, and perhaps even in others there was some portion of the muscular tissue adherent, which gave rise to the peptone reaction. But if peptonuria is really and exclusively associated with involution and reabsorption of the muscular elements of the wound, it might be expected to occur as a product of incipient degeneration of any albuminous tissues arising from other causes. For this reason the organs of animals poisoned with phosphorus were examined for peptone, as an analogy, possibly far-fetched, exists between the degeneration thus resulting and the involution of the puerperal uterus. The results obtained were somewhat various, and the chief definite conclusion that the author thinks himself warranted in making is, that in all cases where the organs experimented on were found to contain peptone, either none or very slight fatty degeneration of the tissue was established, while in cases of marked fatty degeneration no peptone was to be found. In this there is a certain analogy with the cause of puerperal peptonuria, for in the latter the peptonuria comes on before, and disappears with the full establishment of fatty degeneration.—*The Obstetric Gazette*, April, 1885.

Antagonism of Pilocarpine and Ergotine.—Dr. Rabuteau has communicated to the Society of Biology the following results of his experiments with pilocarpine and ergotine: If you inject pilocarpine beneath the skin of a rabbit, it is well known that salivation is produced. If you inject first, ten centigrammes of ergotine, and in ten or fifteen minutes, one centigramme of pilocarpine, salivation takes place just the same. If the two substances be injected simultaneously the salivation is considerably diminished, or even suppressed, but a little later it makes its appearance. The same thing occurs if a dog be used for the experiment. Salivation takes place if ergotine be injected before the pilocarpine; if the two substances are injected together, salivation appears only in from twenty to fifty minutes. If at the moment the salivation appears ergotine be injected, it will be at once arrested. There exists, therefore, an antagonistic action between these drugs—the ergotine destroying the effects of the pilocarpine. But as the action of pilocarpine is a prolonged one, from an hour and a half to two hours, and that of ergotine is very fugitive, the result is that the antagonism is only momentary. Moreover, the action of pilocarpine is local. This is proven by the fact that the effects are the same in cases where the nerves supplying the salivary glands have been cut.—*Revue Bibliographique.*

Malarial Joint Disease.—Dr. Barbere-Bonghini stated, in a communication directed to the Medico-Chirurgical Society of Camerino, that he had met with a number of cases of arthropathy of the left hip in individuals suffering from hypertrophied spleen. His observations led him to the conclusion that the alterations of the spleen, induced by malaria were a not infrequent cause of arthropathies.—*Gaceta Médica Catalana*, April 30, 1885.

Treatment of Incontinence of Urine by Vesical Dilatation.—Dr. Felipe Margarit writes, in the *Gaceta Médica Catalana*, of April 30, 1885, concerning a case of incontinence of urine occurring in a boy, twelve years of age, of excellent physical constitution. The boy had been under the care of a number of physicians, and every form of medicinal treatment had been tried without avail. After giving a number of drugs for a time without obtaining any results, Dr. Margarit determined to try dilatation of the bladder by means of injections. At first only about an ounce of water could be forced into the bladder, but the capacity of the organ increased gradually under the influence of daily injections, until, at the expiration of a month, it would hold upward of seven ounces. In proportion as the capacity of the bladder increased, so did its ability to retain the urine.

Listerism and the Spray.—Mr. J. Knowsley Thornton has just performed eighteen hysterectomies, with two deaths, and says that Listerism with the spray is a great safeguard in hysterectomy.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 20, 1885.

THE INVITATION OF THE AMERICAN MEDICAL PROFESSION TO THAT OF EUROPE.

IT is time for the medical profession to speak in no uncertain voice regarding the confusion in which the management of the next International Medical Congress has become involved. The American Medical Association appointed a committee which tendered to the last Congress, in the name of the American Medical Profession (*not* Association), an invitation to meet in this country. This committee was given, specifically and unqualifiedly, full power to enlarge its numbers, tender the invitations, and organize for the meeting. This authorized invitation was accepted, and a kind of contract between the American and European professions was thus made. The committee then proceeded to organize. The result of its work was approved generally by even the most critical of the medical press of the country. The list of officers was published in the leading journals of Europe. Several hundred gentlemen, in response to invitations of the officers, had signified their intention of being present and reading papers. Matters were thus progressing favorably, there was no complaint and no trouble ; when suddenly comes the American Medical Association and says that this must all be changed. In elegant language the committee is told that some of its most distinguished appointees must be "lifted by the hair and their heads cut off."

The reasons put forward were that the States and Territories should be more fully represented, and that believers in the New Code should be left out. The real facts, we fear, are that a few dissatisfied gentlemen wish to get into prominence in connection with the Congress. There was no sentiment against the work of the original committee, and there would have been no discord and no dissatisfaction now, if it were not for a few turbulent schemers who would elevate themselves at the expense of the good name of the profession. For, no matter what artful aids to justify it may be summoned in the way of parliamentary tactics and appeals to ethical prejudice, or local pride, no good can possibly come out of this new committee ; appointed without authority, containing many names of which the profession knows nothing, or too much, its actions can only create confusion abroad, quarrels and failure at home.

The profession at large did not want it, and will soon, we doubt not, protest against it. The great mass of the doctors of this country wish to have a good Congress, and wish to see the best men in it irrespective of section. They will not forget nor forgive any men who scheme to make the Congress serve personal ends.

There is some misunderstanding, truly, in the minds of certain coteries who regularly attend the meetings of the American Medical Association. That society does not yet represent the whole profession of this country—far from it. It numbers nominally some three or four thousand members, but practically only eight or nine hundred ; while the total number of regular physicians in the country is over sixty thousand. Shall the peculiar views and paltry ambitions of some few of these members be allowed to put the whole profession in disgrace ? We trust that the good sense of the New Orleans committee and the firmness of the original committee will prevent it. At any rate, we beg our readers to keep this fact in mind, that the organization of the International Congress was progressing happily and satisfactorily up to the appointment of this New Orleans committee. If discord and disaster now follow, every one will at least know on whom to fix the responsibility. We beg of its members, therefore, to exercise the greatest forbearance and discretion. Fortunately, there are many among the number of whom we can expect this.

REFORMING A MATERNITY HOSPITAL.

EXPERIENCE shows that the citizens of some parts of our country do not take kindly at first to the application of scientific methods to practical affairs. The recently-appointed superintendent of a Chicago lunatic asylum, for example, is reported to have been knocked down by one of his employees for venturing to place the management more in harmony with advanced psychiatrical views.

We learn from *The Argonaut*, of San Francisco, that a contest is going on now regarding the County Hospital in that city. A young man, of apparently German and Semitic origin, has been appointed visiting physician to the obstetrical ward, and he has discovered therein a most shocking state of affairs, viz. : the ward contained a jar of belladonna ointment, but no nail-brushes ; it was "run" by the nurses and matron instead of the doctors ; the women while waiting, expecting to be confined, were not examined ; the babies after their birth were removed from the mother and sent off to various places, where it is firmly believed they mostly died.

The young gentleman who makes these discoveries, and who kindly sends us a marked copy of a two-column article describing the turbulence of the feelings aroused thereby, seems to be very much in earnest—at least in the matter of being known to the general public as a first-class obstetrician and reformer.

We have no doubt that the San Francisco Hospital has some abuses, and needs some reforms ; we are sure that every maternity ward in the country ought to be conducted upon the thorough antiseptic principles which have produced such brilliant results in this city, Vienna, Paris, and elsewhere ; but it may be that such reforms could be secured just as well without quite so much publicity to the reformer.

RAGS AND INFECTIOUS DISEASE.

The paper-manufacturers of the country have engineered matters very skilfully. They have succeeded in working upon public opinion until sanitary officers or medical men cannot affirm that imported rags ought to be disinfected without incurring the charge of being in collusion with a company which undertakes to do this disinfection. The Treasury Department itself has exhibited a curiously tortuous and uncertain policy regarding the matter, illustrating, if nothing else, the sore need that exists of its having some more authoritative and better-selected advisers. This policy has culminated in the Secretary leaving the whole matter in the hands of the different States and port officers. Whether rags will be disinfected, therefore, will depend upon the sanitary peculiarities of these officers. Already, under the influence of this decision, it is stated that a ship-load of rags, which would have to be disinfected at New York, is to be sent on to Portland, Me.

Fortunately, for practical purposes, most of the health officers of the country are in very substantial harmony as to the modes of disinfection and quarantine.

The opinion of these officers, and of the best health authorities generally, is that imported rags should sustain careful inspection, and, if need be, disinfection. The best methods of securing a sanitary history of the rags—and that is what the ship should supply—have not yet been devised, and, therefore, some trouble must for the present ensue. It is much wiser and more economical, meanwhile, to be on the safe side, and Health Officer Smith will get the hearty support of the profession and the laity if he takes firm ground in defence of the public health.

It should be remembered that cholera is not the only danger which we must avoid. Whether it has ever been imported in rags or not, other diseases, almost as destructive, have been so conveyed.

THE ALLEGED CHOLERA VACCINATIONS.

The claims of Dr. Ferrán to be able to furnish protective inoculation against the cholera, still remain unestablished. His experiments are naturally received with profound distrust by pathologists, for it seems *a priori* impossible that, by the methods described, he could obtain protective results. The most probable explanation is that he is not working with pure fluids.

The report of the Committee of the Madrid Academy of Medicine, which appears to embody a careful review of Ferran's experiments, confirms the statement that the comma bacillus passes through the various stages described by Ferrán, but adds the significant fact that "bodies other than this micro-organism are also found in the cultivation-fluid." Cultivations of the bacillus were injected hypodermically into guinea-pigs. In all cases the injections caused severe constitutional disturbance, and finally death; but the symptoms were not choleraic, and the principal changes were observed in the blood, in which fluid also the bacilli were found. Here, again, we find different results from those of Koch, Cheyne, and others. The cultivation-fluids were also injected into eleven human beings, with the result of causing constitutional disturbance, fever, vomiting, and diarrhœa.

As to preventive action, the Committee say that the general results obtained by Ferrán are absolutely confirmed. One inoculation of the culture-fluid prevents the pathogenic action of a second inoculation of pure cholera bacilli. "Hence a means of averting cholera has been discovered."

It is added, as a matter of interest, that Dr. Ferrán himself, having suffered one morning with a looseness of the bowels, causing two unusual evacuations, found in the second true specimens of the comma bacillus, which he used for a series of cultivations.

As for his practical work in inoculating, we learn that in Valencia he has operated upon 8,000 persons, including some physicians. At the Alcira hospital all the inmates were inoculated except two; these died of cholera later.

A report comes that at Alcira 7,128 persons were inoculated once, of whom 7 were attacked with cholera and 2 died; that of 3,011, inoculated twice, none died. Meanwhile, among the 3,000 or 4,000 non-inoculated, 73 cases occurred, with 39 deaths.

Despite all the above, there is considerable probability that Dr. Ferran is only inoculating his countrymen with a mild type of septicæmia.

THE STATE AND THE PHYSICIAN.

The *Hour*, a weekly journal of this city, has been discussing the subject of physician's fees, and comes to the conclusion that they should be regulated by the State, so that no doctor can have the right to charge more than a maximum of, for example, five dollars. As regards this, we can only say that if the State would at the same time arrange that the doctor never got less than a minimum of, say one dollar, there would probably be no objection to establishing a maximum. But it would not be fair to carry out the *Hour's* brilliant suggestion of trimming at one end only.

Our progressive contemporary the *Sanitary Engineer*, in a recent issue calls attention to another matter in which the State may, with much more justice and effect, lay its commands upon the doctor. This relates to the physician's connection with contagious diseases. The doctor ought to be able to recognize contagious diseases; he ought to know how to manage them, so as to prevent their spread; he ought to see that he personally is not a means of contagion. He ought to be made to feel a responsibility regarding these points. It is hardly settled as yet, however, to what extent the State can call him to account, or compel the physician to use his knowledge in the prevention of disease. We have always held, with English authorities, that the Government has no moral right to compel physicians to contribute their services and special skill toward preventing disease, without any compensation.

The State can, with justice, no more do this than it can require an attorney-general to give his legal services gratis. We cannot agree entirely, therefore, with the *Sanitary Engineer*, that "a community has the right to demand of its physicians that they shall use their knowledge for the prevention as well as the cure of the disease," unless it is meant that they receive a *quid pro quo* for the first, as they do for the second.

ADVOCATING PROFESSIONAL ADVERTISING.

THE *Medical and Surgical Reporter* thinks that "refined, specious, and respectable methods of advertising," may be resorted to without harm to the dignity and standing of the profession, and that such methods are only just to its younger members.

We cannot quite agree with our blonde contemporary. There are a great many of these "younger members" who cannot see why they are not, after a two years' practice, entitled to the same honors and emoluments as those possessed by men who have worked for thirty years. Every now and then some one voices this feeling, which may be referred to as the "Bitter Cry of the Two-year-olds." But it is a feeling based somewhat upon a misapprehension. For it never can or should happen that the young practitioner is at once the equal of his elders. Advertising will not help the matter, and, apart from any question of propriety, it is a short-sighted policy which encourages or justifies the advertising of professional skill. If such practice became allowed, and we stood exactly on the same plane as the grocer or tradesman, every doctor would have regularly to advertise. While dignity and truth would thus be sunk, no one would be a gainer, and a large per cent. of professional income would have to go into the hands of the printer and publisher. There is a legitimate advertisement which comes from capable and honest teaching, from the publication of scientific and clinical work, and from the insertion on proper occasions of ordinary professional cards.

GEOGRAPHY AND MEDICAL SCIENCE.

IT is much to be deplored that any feeling of sectionalism has been aroused in connection with the next International Medical Congress. As the *Medical News* has well stated, this Congress is a purely scientific body. In its organization and membership it aims to represent medical science, not geographical districts; hence, in selecting its officers, the fact that a certain State, for example, has an annual cotton crop of one and a half million of bales, as forcibly stated by a Western contemporary, should carry very little weight.

It must always be the case that in younger and growing countries the sciences will be less advanced. In the Eastern and Middle States there are not yet the institutions, the associations, or the material help which enables us to raise medical scientific work to a level in amount and quality with that of Europe. In these respects we are rapidly advancing, and already a considerable amount of first-class work is being done, while the means and opportunities for more are continually multiplying.

But if even the most ardent patriotism cannot blind us to the above facts, neither can any amount of sectional pride deny that, in the same measure, the East has in medical and literary work been able, through its greater age and greater accumulations of capital and experience, to keep in advance of the younger sections of the country.

In twenty or thirty years the story may be different, but who can deny the literary and scientific supremacy of the older sections now? And what blame or what shame is incurred by admitting it? *Per contra*, the youth who arrogates manhood and maturity makes a disagreeable spectacle of himself. If one examines the medical works written by American authors in the past thirty, or even one hundred years, works which have brought fame and credit to American medicine, it will be found that at least ninety-five per cent. of them were written and published in the older sections of the country by men who lived in these sections. We need only refer to the representative works of Gross, Emmet, Bartholow, Loomis, Thomas, Sims, Lusk, Williams, Hammond, Roosa, Duhring, Flint, Dalton, Ashhurst, Delafield, Satterthwaite, Bumstead, and others, works covering every department of medicine.

While every year witnesses fresh progress elsewhere, we believe it may be safely said that the periodical literature also of the older sections still retains the lead which age and experience would naturally give it.

We call attention to these facts, for such they are, simply in the belief that the members of the profession will recognize it to be just and natural that an older country will be in advance, in some directions, of a new one, and that some extra consideration is due, not to geographical sections, but to age and maturity.

The International Medical Congress cares not a rap that a State has two hundred millions of taxable property. It asks for its scientific men, its teachers, its literary workers, and its institutions of learning. These are what form the basis of representation.

News of the Week.

IS TOXIC ENTERITIS CAUSED BY CORROSIVE SUBLIMATE AS A SURGICAL APPLICATION?—"THE MEDICAL RECORD of March 14th contains an article under the above heading, in which eleven cases occurring in the New York Hospital are cited as examples of toxic enteritis arising from the use of bichloride of mercury as a surgical application. Of six of these we have a personal knowledge, and think that if a fuller history of them were given, there would be, in the minds of most readers, a very reasonable doubt as to whether the alleged toxic symptoms were due to the bichloride or to other concurrent conditions." The cases are then given in detail. In No. 1, there was septicæmia; in No. 2, purulent peritonitis; in No. 3, tuberculosis; in No. 4, chronic bone disease and amyloid kidneys; in No. 5, no relief of diarrhœa after stopping bichloride; in No. 6, a new operation at time when bichloride was stopped. "It will be noticed that in all the foregoing cases diarrhœa might be easily accounted for by the other existing conditions, even if no sublimate dressings had been used. It will also be noticed that in none of them did any salivation, or sponginess and soreness of the gums occur, nor was any fetor of the breath noted.—DR. E. C. SPENCER, in *Northwestern Lancet*.

A SUSPICIOUS CASE.—A suspicious case, strongly suggesting cholera, was brought in by one of the Bellevue Hospital ambulances on Monday of this week. The patient, a middle-aged man, was found on a canal-boat at one of the up-town East River piers, having come there from Weehawken. On the morning of the above-named day he felt perfectly well at nine o'clock, but two hours

later he was attacked with vomiting, purging, cramps, rice-water-like stools, cold skin, cyanosis, and rapid and feeble heart action, and in this condition was brought to the hospital. The possibility of cholera was at once suggested, and one of the attending physicians, who has seen much of the disease, remarked that if a cholera epidemic were now prevailing, he should regard the case as a typical one of the disease. It was deemed prudent to notify the Board of Health, and under its direction the man was transferred to the Reception Hospital at the foot of East Sixteenth Street. He quickly responded to treatment, however, and by night was considered out of danger. Microscopical examinations of the dejecta were made at the Carnegie Laboratory. They contained some fecal matter. Shreds of mucus and some comma bacilli were also found. Plate-cultures of the latter, however, showed them to be the microbes of sporadic rather than of Asiatic cholera. An investigation by the Health Board revealed the fact that the man had in all probability been eating tainted meat, and that to this his symptoms were probably due.

Scientific Inspection versus Quarantine.—There is some difference of opinion in New Orleans concerning quarantine methods. Some of the business men have given to the State Board of Health money to be used in substituting what is described as "a scientific method of disinfection and sanitation" for the old system of absolute non-intercourse with infected ports, and long quarantine against other ports. One death in the city, said to have been caused by yellow fever, has led the Cotton Exchange to demand a restoration of the old system, and other exchanges have called for an extension of the quarantine.

Bills that Failed to Become Laws.—Governor Hill did not sign the following bills, passed by the New York Legislature: To prohibit the sale of cigarettes to minors under the age of fourteen years; To prescribe the preliminary education of medical students; Of a suit against the estate of a party deceased.

Dr. Gunn's Medical College Bill was very properly vetoed by the Governor. The strongest argument Dr. Gunn made for his institution was that he believed he could do as well as some other colleges in the State.

New York Infant Asylum.—An attack on the management of this institution was made in the daily papers recently. The State Board of Charities also gave a not very favorable description of its management. We have good reason to know that this institution is not conducted in a model manner in some respects, the main trouble being excess of petticoat-rule. There are, however, no glaring defects, and a marked improvement has taken place since the appointment of a medical board.

A Bad County Asylum.—The State Board of Charities has sent a committee to examine the Onondaga County Asylum. Serious defects in its management are reported.

Precautions against Cholera.—At a recent conference in this city of the Health Officers of the ports of New York, Boston, New Haven, Brooklyn, and Baltimore, and the State Board of Health of New York, the following quarantine regulations were adopted to prevent the introduction of cholera and other diseases into the United States the coming summer, to go into effect immediately: The maximum period of incubation of Asiatic cholera may, for quarantine purposes, be assumed to be eight days, and that in case of the disease occurring on vessels during the voyage hitherward, the quarantine of observation of persons should extend to eight days from the last date of possible exposure. That for the fumigation of closed spaces, sulphurous acid gas may be commended, from two to three pounds of sulphur being burned for each 1,000 cubic feet. That for disinfection of baggage or other fomites, reliance may be placed on fresh chloride of lime, bichloride of mercury, or dry heat to 230° F. That in view of the danger of other contagia, as well as that of cholera, all rags imported to this country should be disinfected either at place of departure or on their arrival here. That if such disinfection be done abroad, it be required that either the rags be boiled for not less than thirty minutes and dried before baling, or treated with superheated steam for not less than eight minutes, and in such manner as to be heated to or above 212° F. in every part.

Small-pox in New York.—On June 9th two thousand immigrants were brought to this port, and were transferred at once by the Emigration Commissioners to the western end of Ward's Island, there to await quarantine. On June 13th a case of small-pox appeared among them. On June 14th two other cases were found. Attempts were immediately made to isolate the two thousand, and keep the neighboring Lunatic Asylum from being infected. Apparently, the efforts to do this, and to prevent a further spread of the disease, were successful, as up to date of writing no new cases have been reported. Some justifiable criticisms have been made upon the action of the Emigration Commissioners in, as it were, dumping two thousand infected paupers within the city limits, subjecting them to a very imperfect quarantine.

Dr. Morris Mattson died on June 13th, at his home in this city. He was in the seventy-seventh year of his age.

The State Board of Health has been sadly crippled by the action of Governor Hill in vetoing the bill appropriating $15,000 for its use. Perhaps no immediate ill results will follow, but it is a step backward and indicates a most reprehensible short-sightedness on the part of the State's executive officer. It is, at any rate, gratifying to hear the uniform praise given to the Board by the press of the city.

Cholera in Spain.—Cable reports show that cholera is spreading in Spain with much rapidity. In one day the number of new cases reported was, in Madrid, 4; in Valencia, 17; in Castellon de la Plana, 58; in Murcia, 98; in the whole province of Murcia, 171; in Arajunez, 1; making a total of 234. The mortality is a little less than fifty per cent. The disease appears to be spreading along the coast to the northward. The people are reported to be in a state of panic, especially those living in the smaller places. The latest reports regarding Ferràn's inoculations show them to be an utter failure.

Reviews and Notices.

The London Medical Student, and other Comicalities. Selected and Compiled by Hugo Erichsen, M.D. Detroit, Mich.: Dr. H. Erichsen, 11 Farmer Street.

Dr. Erichsen has evidently made up his mind that the medical profession require, above all things, to laugh more. Some time ago, it will be remembered, he launched forth a collection of "Medical Rhymes," some of which were decidedly humorous and mirth-provoking. The appreciation bestowed upon that effort has induced him to "try again."

This time he has collected a large number of medical anecdotes that might be appropriately labelled as good, bad, and indifferent. He has also rescued from forgetfulness a not over-witty portraiture of medical student-life in London, which appeared in *Punch* about fifty years ago. It may be said of this "London Medical Student" what a gentleman remarked who thought he was listening to a humorous lecture by Mark Twain, but was, through some mistake, made to hear the prosy sermon of a temperance advocate; when this victim's wife asked him whether he had found Mark Twain funny, he replied: "Oh, yes; he was funny, but he wasn't real funny!". So we may say that the "London Medical Student" is rather less funny than he might be, or than he evidently believes himself to be.

Nevertheless, the book before us may answer the purpose of beguiling some weary hour of the physician's life with smiles and occasional laughter, and as such it recommends itself to the attention of the profession.

Endemic Goitre, or Thyrocele. By William Robinson, M.D. 12mo, pp. 66. London: J. and H. Churchill. 1885.

This monograph was the author's thesis for the degree of Doctor of Medicine of the University of Durham, for which the gold medal was awarded in 1884. The most valuable chapters are those on the relation of the disease to cretinism and allied disorders, and on the geographical distribution of the malady. In regard to the exciting cause, the author has no new theory to offer, while discussing fairly the probable effects of heredity, cross marriages, vaso-motor paresis, etc. His researches have led him to regard potable water as the *vehicle* of the cause. The exact *nature* of the latter he does not regard as at present known. His study of the geographical distribution of the disease and the relation of this distribution to geological formations, is very complete, and will be of great service to all future writers on the subject. Under the head of treatment, comparison is made between results following the use of iodine, mercuric iodide, dilute fluoric acid, and quinine; the latter has sometimes proved useful, suggesting a miasm as an exciting cause. The surgical resources are setons, incision, injection of sac (in the cystic variety of the disease), and partial or complete excision.

Operative Surgery in the Calcutta Medical College Hospital: Statistics, Cases, and Comments. By Kenneth McLeod, A.M., M.D., F.R.C.S.E., Professor of Surgery, Calcutta Medical College, etc. 8vo, pp. 351. London: J. & A. Churchill. 1885.

The observations here recorded extend over a period of five years, and give a faithful portrayal of the surgical history of the above-named institution during that time. Comparisons are also made with the results published by Sir Joseph Fayrer, the author's predecessor, as first surgeon to the hospital. The author frankly admits, in his preface, the fallacies attending statistics of surgical operations, but, animated by a desire to state facts as they have occurred, and free from any desire to prove this, or disprove that, theory, he has succeeded in giving us a very readable volume. His study of the climatic and sociological conditions attending his work has been thorough. He describes the native temperament as essentially bilious, or bilio-neurotic, and notes, on a comparison with Europeans living in India, "a difference in pathological proclivities depending on fundamental diathetic distinctions." Interesting facts are the rarity of arterial disease in India, and also that of stone; but suppurative complications (particularly after miasmatic diseases), rectal troubles, and hæmatocele, are very common. Stone is more frequent in the provinces than in the city of Calcutta. Elephantiasis is especially common. Of this he distinguishes two forms as occurring in the scrotum, the ordinary more or less solid tumor and the "lymph scrotum." The latter is quite infrequent, and appears to be associated with filiariæ, which he has never found in the former. An interesting table of six cases of hepatic abscess is presented. All were treated by incision under antisepsis. Three proved fatal, two from suppuration, and one from dysentery. The other three made good recoveries. The author has tried, with success, what he calls "nerve-splitting" in cases of lepra anæsthetica. In some cases of the latter he has found the nerve-trunk greatly enlarged, with a softening of the interior, of a curdy nature. The ulnar nerve seems to be particularly liable to this form of disease. The native subject he regards as an extremely unfavorable one for any operative procedures. The sanitary improvement of the Calcutta Hospital, together with the introduction of Esmarch's bandage and Listerism, have greatly lessened the percentage of mortality. On the whole, the book is very entertaining, as well as instructive.

A Treatise on Amputations of the Extremities and their Complications. By B. A. Watson, A.M., M.D., Surgeon to Jersey City Charity Hospital, etc. 8vo, pp. 762. Philadelphia: P. Blakiston, Son & Co. 1885.

This volume is an "encyclopædic monograph containing the important facts, theories, and arguments relating to amputations of the extremities and their complications." The author's aim has been to collect facts on this subject from English, French, German, and American literature. He does not lay claim to originality, but, of course, introduces, in their proper places, those observations which his own experience has led him to make on the general subject. Under the division of "complications," the general subject of the treatment of wounds is discussed, with an outline of the present views on germs and germicides, for, in the words of the preface, "the complications of amputation-wounds are essentially the same as those which pertain to any solution of continuity involving the various tissues of the body." A great service has been done to the profession by the insertion of a translation of Gaujot's and Spillmann's writings on artificial limbs. This is the fullest exposition of the subject we have yet seen in an American text-book. Too much praise cannot be given to the typographical appearance of the work. The illustrations are marvels of clearness, and do, what is not always the case, elucidate the text.

Modern Therapeutics of the Diseases of Children, with Observations on the Hygiene of Infancy. By Joseph F. Edwards, M.D., Editor of the *Annals of Hygiene*, etc. 8vo, pp. 346. Philadelphia: D. G. Brinton. 1885.

This is the fourth volume of the "Modern Therapeutic" series, and will well sustain the good reputation made by its predecessors in this quarter of the literature of therapeutics. Its collation of facts from the writings of foreign and home authors is accurate and complete. It will save the busy practitioner many laborious hours. It is difficult to see what mission many medical books have, but the great variance of opinion between equally qualified men—as shown in this volume—is itself a vindication of its right to exist. Order can come out of our

present therapeutic chaos only by a comparison of ideas and a revision and condensation thereof in the light of clinical experience. The style of the book is simple and straightforward. Worthy of especial commendation are the valuable indices of diseases, remedies, and remedial measures and authors, simplifying to a minimum the work of reference.

CONTROLLING SEX IN GENERATION. By SAMUEL HOUGH TERRY. 12mo, pp. 147. New York: Fowler & Wells Co. 1885.

THE author claims to have discovered the law by which it is possible to produce male or female offspring at will. In brief, it is that the stronger of the two parents at the moment of conception controls the sex of the embryo, breeding the opposite to him or herself. The theory is by no means novel; it has been frequently and ably advanced and with much better and more scientific reasoning and experiments than in the confused and hasty work before us; indeed, our old friend, Dr. Riccabocca, in Bulwer's "My Novel," has stated it is derived from the ancient philosophers. But the proof is still lacking that the explanation is correct, and every one can in a moment recall from among his own acquaintances so many "exceptions," that he will be left in grave doubt whether the rule is the exception or the exceptions are the rule.

THE STUDENT'S HANDBOOK OF FORENSIC MEDICINE AND MEDICAL POLICE. By H. AUBREY HUSBAND, M.B., C.M. Fourth and Revised Edition. Pp. 604. Edinburgh: E. & S. Livingston. London: Balliere, Tindall & Cox. 1883.

THIS is a small work, but it is a most thorough and practical compendium of the subject with which it deals. It offers enough for students and for most physicians.

The author's preface to the fourth edition was written in 1882, so that we can hardly call the present work a perfectly fresh one. It is very well printed and substantially bound.

TRACTS ON MASSAGE. No. I. THE ART OF MASSAGE. Translated from the German of Reibmayr, with notes. By BENJAMIN LEE, A.M., M.D., Ph.D., late President of the American Academy of Medicine, Member of the American Medical Association, etc., etc. Philadelphia: Benjamin Lee, M.D., 313 S. Fifteenth Street. 1885.

THIS little book, appropriately called a tract, is the first of a series which Dr. Lee proposes to issue, embodying the substance of the treatise entitled, "Massage and its Utilization in the Various Departments of Medical Practice," by Dr. Albert Reibmayr, of Vienna. In this first tract the author describes in simple terms the various manipulations of massage which he groups under the four heads of stroking, friction, kneading, and percussion. The value of the little work is further enhanced by copious notes by the translator. An appendix contains a bibliography of the most recent works on massage in English, French, and German.

MICRO-CHEMISTRY OF POISONS, INCLUDING THEIR PHYSIOLOGICAL, PATHOLOGICAL, AND LEGAL RELATIONS; with an Appendix on the Detection and Microscopic Discrimination of Blood. Adapted to the Use of the Medical Jurist, Physician, and General Chemist. By THEODORE G. WORMLEY, M.D., Ph.D., LL.D. With ninety-six illustrations upon steel. Second edition. 8vo, pp. 784. Philadelphia: J. B. Lippincott & Co. 1885.

THE title "Micro-chemistry of Poisons" hardly does justice to Professor Wormley's elaborate work, which is really a very complete treatise upon toxicology.

The present edition is a decided improvement upon the former one, and debars the criticism which that suggested of being somewhat antiquated in matter and faulty in scientific method.

In the present volume the author has revised the chemical nomenclature and added many illustrative cases, new tests, a new chapter on Gelsemium Poisoning, and an appendix on the Blood. The subjects of poisoning by potassium chlorate, post-mortem diffusion of arsenic, and the nature of ptomaines are also added. Two new steel plates, including twelve illustrations of microscopic crystals, and cuts showing the size of the red blood-cells of six different mammals, together with a chromo-lithograph of blood-spectra, are among the other additions to the work.

The author begins with a chapter in which he describes the evidences of poisoning and the various methods of studying these evidences.

He then takes up the different inorganic and organic poisons, giving their chemistry, physiological effects, treatment, post-mortem appearances, chemical and microscopic tests.

The appendix on the Blood is a very useful contribution. The book is made especially valuable also by the numerous and exquisitely executed steel cuts of microscopic crystals. This work is done by the author's wife. There is an elaborate table at the end of the book which will prove most helpful to the chemist.

We observe no reference to the toxicology of the aniline dyes. The chapter on ptomaines is also by no means so complete as it might be made. In general, however, the author appears to have dealt with his subject carefully and thoroughly. The style is good, the descriptions are clearly given, and the book will undoubtedly serve a most useful purpose in legal medicine and toxicological study.

THE OSTEOLOGY OF AMIA CALVA, including certain Special References to the Skeleton of Teleosteans. By R. W. SHUFELDT, M.D., Captain Medical Corps, U.S.A. Washington: Government Printing Office. 1885.

THIS monograph contains a review of two memoirs upon the osteology of this interesting form, and also some personal observations of the author, the result of an examination of a specimen of this fish caught near New Orleans in 1883. It forms a part of the annual report of the Commissioner of Fish and Fisheries for 1883.

DEPARTMENT OF AGRICULTURE. CONTAGIOUS DISEASES OF DOMESTICATED ANIMALS. Investigations by the Department of Agriculture, 1883–1884. Washington: Government Printing Office. 1884.

THE present report contains the results of special investigation at the Washington Experimental Station, and in the West. The reports on the Outbreak of Ergotism, on Pleuro-pneumonia, on Swine Plague, and Cattle Fever, all contain much original and collected statistical matter, reflecting great credit on the Department. In the line of experimental culture of micro-organisms some of the best work in the country has been done by Dr. Salmon and his associates.

CHINA: IMPERIAL MARITIME CUSTOMS. Special Series, No. 2. Medical Reports for the Half Year ended March 31, 1884. Shanghai. 1884.

TENTH REPORT OF THE STATE BOARD OF HEALTH of MINNESOTA. January 1, 1883, to August 1, 1884. St. Paul, Minn. 1884.

PROCEEDINGS OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY. Vol. VI. September, 1883, to June, 1884. Edited by Publication Committee. Philadelphia. 1884.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Twentieth Annual Meeting, 1884. Boston: Published by the Society. 1885.

ANNUAL REPORTS OF STATE MEDICAL SOCIETIES. Illinois, 1884; Kentucky, 1884; Colorado, 1884; Connecticut, 1792–1829; Georgia, 1884; Wisconsin, 1884.

WE regret that lack of space prevents us from giving such notice as many of the above publications deserve.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Nineteenth Annual Convention, held at Long Branch, N. J., June 9 and 10, 1885.

FIRST DAY—TUESDAY, JUNE 9TH—MORNING SESSION.

THE meeting was called to order by the President, DR. BARKER, of Morristown.

In the absence of Rev. E. B. Tompkins, DR. STEPHEN WICKES, of Orange, offered the opening prayer.

DR. S. H. HUNT tendered

THE ADDRESS OF WELCOME.

After giving the Society a hearty greeting, he dwelt at considerable length upon the progress made by the profession during the past few years.

The minutes of the last annual meeting were then read and approved.

The Committee on Business, in their report, urged that discussions upon all topics be limited in time to five minutes, and that scientific papers be read early enough to secure the attention they deserve.

The delegates to corresponding societies, in their report, stated that at the International Congress, at Copenhagen, the European physicians ignored the American members in not electing any of them to office. This was thought to be a great breach of professional etiquette.

FIRST DAY—TUESDAY, JUNE 9TH—EVENING SESSION.

ANNUAL ADDRESS BY THE PRESIDENT,

DR. P. C. BARKER, who took for his subject the

PRESENT STATUS OF THE GERM THEORY OF DISEASE.

He began by saying that the literature upon bacteria will become the romance of medicine. He then referred to the various epidemics since the fourteenth century, and said that the great dread of fatal epidemics stimulated experimental investigation into the cause of such diseases. Pasteur's views in regard to fermentation were dwelt upon. He claims that each micro-organism gives rise to a peculiar fermentation, and that when such a fermentative process is established in living tissues, the various manifestations of the disease to which the organism gives birth are soon made evident.

When Lister recognized the importance of germs, he at once made use of antiseptics in the treatment of wounds, thereby introducing a method far superior to any which antedated him.

These micro-organisms are not easily destroyed at ordinary temperatures, but high and low temperatures, and absence of moisture, deprive them of their activity.

The spores of these organisms are not easily destroyed, as they have a double envelope which protects them from external injurious influences.

Erysipelas has been reproduced in both the lower animals, and in man, and such artificially-produced erysipelas is supposed to have rendered the individuals less susceptible to a second attack of the same disease.

Dr. Ferran's experiments were alluded to. He has inoculated many people with cultivations of the cholera spores, and he claims that such inoculated persons are not liable to the development of malignant cholera.

He inoculates in the lower part of both arms. During the following few hours, pain in the arms, headache, loss of appetite, and fever (104 F.) are experienced. Sometimes these symptoms continue two or three days, but never become severe, and in no case has life been sacrificed.

Experimentation upon the lower animals has shown that they present different degrees of susceptibility to the various specific germs.

In order that inoculation of an animal may be satisfactory in result, it must be shown that the specific germ used in inoculating the animal is reproduced in its tissues, and that the disease of the animal corresponds with the disease as spontaneously developed in the individual from whom the virus was obtained.

Since investigations have shown so much of importance concerning the relation of germs to disease, sanitary science has risen into great prominence, and it has done very much toward stamping out the existence, and in preventing the spread of contagious diseases.

In the case of the Plymouth epidemic gross negligence was manifest, for, as the result of the contamination of the air by the poison of the excreta of one typhoid fever patient, many valuable lives were sacrificed.

PREVALENT DISEASES.

The Standing Committee stated that each county society was in hearty sympathy with the various district societies in regard to all matters of sanitary legislation.

It further reported that the severe cold weather of the past winter had caused much catarrhal inflammation of the air-passages.

In the vicinity of Englewood there were many troublesome cases of infantile diarrhœa, and a few cases of scarlatina and diphtheria. In Burlington County there were many cases of severe tonsillitis. In Camden County there were many cases of intermittent fever and quite a large number of cases of diphtheria, also a large number of cases of rheumatism, twenty cases of scarlatina, and a small epidemic of measles. Cumberland County had been unusually healthy. In Essex County, scarlatina, diphtheria, and measles had been epidemic; there were also many cases of mumps, followed in one instance by facial paralysis, in another by chorea.

There were many cases of severe pneumonia in Burlington County. Mercer County has been exempt from serious diseases. In New Brunswick there were many cases of severe typhoid fever. It was reported that cocaine had been extensively used in painful diseases of the ear, and with success. Quinia sativa was used with good results in chorea. Jaborandi has been employed with benefit in the first stage of pneumonia, and it has apparently shortened the disease.

PRELIMINARY EXAMINATIONS.

The Corresponding Secretary (Dr. Elmer) stated that each county society should constitute its President, Vice-President, and Secretary, an Examining Board to examine such persons as wish to study medicine in the prescribed English branches. He also stated that any person in good standing in the County or the State Medical Societies, could, with the indorsement of the President of his County or State Medical Society, and on payment of initiation fee, become a member of the American Medical Association.

The Committee on Medical Jurisprudence reported that experts are chosen in the various counties of the State in the same manner. That the Judge may select such experts in any given case as he may consider qualified for the work, and that he, the Judge, shall have power to fix upon the sum to be paid such expert, or experts, for services rendered. The payment of money for expert testimony shall be made by the parties in whose interest the testimony is given.

SECOND DAY—WEDNESDAY, JUNE 10TH—MORNING SESSION.

DR. JOHN W. WOOD, of the Trenton Asylum, read an interesting paper on

GENERAL PARESIS.

He stated that of all diseases of the brain none are more grave or important than general paresis. It is grave because of its incurability, and it selects its victims from

individuals in middle life. It is not mentioned in works on general practice, or in lectures in medical colleges, for which reason it was brought before the Association. It was first recognized as a distinct form of mental alienation by Bayle, in 1822, and was first announced in the United States by Dr. Beel, of the McLean Society of Boston, in 1843.

The English, American, and French writers all regard it as a distinct form of mental disease. The German writers still adhere to the doctrine of duality. It has been steadily increasing in frequency. In 1867, in the Trenton Asylum, there were but *two* cases. The average admission during the last three years has been eight. It is a disease of the brain, especially of the gray matter.

The symptoms, motor and psychic, are, according to the views of the author of the paper, that mental symptoms are first manifested, and consist of a change of character, as manifested in taste and temperament and moral habits; of the motor symptoms, first an indistinct articulation, and finally an inability to coödinate the movements of the lower extremities. The peculiarity of the symptoms, both mental and motor, is that they are steadily progressive from the very outset of the disease.

The disease is divided into three stages: 1, the prodromic; 2, the inability to articulate and difficulty in locomotion, with mental enfeeblement; 3, complete paresis, with mental extinction. The duration of the disease from its commencement is about four years, and rarely occurs prior to the thirty-fifth or after the fifty-fifth year. The prognosis as to recovery is uniformly unfavorable. The causes predisposing are age, sex, and hereditary tendency. It seldom occurs in the female, and in 127 cases in the Trenton Asylum there was distinct hereditary tendency in 36, and in addition to this, 18 were the offspring of intemperate fathers or mothers. The exciting causes are sunstroke, and any excesses that vitiate the normal healthy standard of the system, particularly alcoholic and venereal excesses.

Treatment.—During the excited stage, the bromides, chloral hydrate, and peraldehydes were advised. The hydrobromate of hyoscin has been used somewhat extensively, and with no other result than a dry throat and nauseated stomach. Dr. Girma's experiment with ergotin, as recommended in the *American Journal of Insanity* for October, 1884, was faithfully tried in twelve cases in the Trenton Asylum, with no favorable result whatever. The epileptiform seizures were mitigated in severity and diminished in frequency by the exhibition of the bromides (*i.e.*, potass., sod., and am.).

Dr. H. H. James, on account of sickness, could not be present to read his paper on "Toleration in Medicine."

The report of the Committee on

HOW TO PREVENT UNLICENSED PERSONS FROM PRACTISING IN THE STATE,

stated that the prosecuting attorney of each county can bring any such case before the court, and fines be levied or other such punishment inflicted as the Court deems wise.

The Committee on the Army Medical Museum and Library of the Surgeon-General's Office reported that a sufficiently large appropriation was made to secure the erection of a fire-proof building for the protection of the valuable Surgeon-General's Library.

EXAMINING BOARDS.

The Committee on Education reported that there should be *two* examining boards, each board to have five members. One of the boards should be assigned to the northern section of the State, the other to the southern section. These boards should report, one week prior to the time of the State Medical Society's meeting, any students examined and any other work done in this connection.

It further reported that the power to license and the power to examine should be exercised by different boards. It urged that all applicants for license to practise medicine in New Jersey should be examined rigidly in the various medical branches, and that no person be allowed to practise, who shall not show a satisfactory intelligence upon all topics examined upon. The Committee doubt the propriety of securing new legislation upon this matter, but urge pushing the power already vested in the State Society.

It also urges courtesy on the part of the Society toward homœopaths, but a stanch support of the principles of the old school of medicine.

It was thought that the Governor of the State should have the power to grant a license to any one wishing to practise medicine in New Jersey, if such an applicant shall have passed a satisfactory examination before an impartial and properly organized Board of "Examiners."

Dr. J. L. Bodine objected to the carrying into effect the report as read, as he thought such legislation as recommended would not be recognized by the laity, and therefore the Medical Society would fail of the recognition it deserves in matters of this character.

Committees appointed by the State government have consisted of regulars, homœopaths, and eclectics, such appointments being very obnoxious to the Society; it was therefore urged that the Governor should not have such power.

Dr. E. M. Hunt thought it was wise that the State required the deposition of a diploma when any physician wished to practise in the State. He also thought it unwise to attempt to carry out the suggestions recommended in the report of the Committee on Education before the Legislature or before the State Board of Examiners.

Dr. Stephenson stated that the homœopaths do not rest in their practice upon the principle "Similia similibus curantur," but upon the system of *proving* all drugs and remedies, vegetable and mineral. He also said that a prominent homœopath said to him that a homœopath need only know the symptoms caused by ingestion of drugs in health, to practise successfully their line of medication.

The Committee on Lunacy asked to be discharged, as they were unable to accomplish the work which they recognized as important. The inability to execute the work has been due to the inefficiency of some of its non-professional members. The motion to discharge the Committee was lost.

Dr. Quimby stated that at New Orleans a Joint Committee was formed to alter or add to the suggestions of the original Committee of the American Medical Society, in relation to the work to be done by the Association at Washington in 1887.

Committee on Treasurer's Account reported receipts, $1,448.19; disbursements, $614.77; balance, $883.42.

Dr. Stephen Wickes read the Report on By-laws. No essential alterations.

Dr. Hunt moved that Cushing's Manual be used as a parliamentary standard in all discussions at meetings of this Society. Seconded and carried.

The Committee on Honorary Membership (Dr. H. R. Baldwin, Chairman) had no report.

The following are the delegates from the various corresponding societies:

Connecticut, Dr. F. E. Beckwith; Rhode Island, Dr. Anita E. Tyng; New York Association, Drs. J. P. Garrish, E. S. F. Arnold; Pennsylvania, Drs. W. R. Hoch, T. D. Dunn, Albert Fricke, and M. O'Hara.

The Society was favored with a very interesting speech by Professor Pancoast, of Philadelphia, by invitation.

Delegates to American Medical Association—Drs. David Warman, Benjamin, William Pierson, Alexander J. Rogers, William L. Newell, Joseph Parrish, J. W. Condict, and S. T. Fisher.

Delegates to Connecticut Medical Society—Drs. William K. Newton, D. C. English, and John Cook.

Delegates to Massachusetts Medical Society—Drs. Abraham Coles, D. A. Currie, Bole, and B. A. Wollington.

Delegates to Pennsylvania Medical Society—Drs. O. B. Gross, George H. Harrison, and J. P. Davis.

Delegates to Rhode Island Medical Society—Drs. E. M. Hunt and Edward North.

OFFICERS FOR ENSUING YEAR.

President—Dr. Joseph Parrish.
First Vice-President—Dr. Charles J. Kipp.
Second Vice-President—Dr. J. W. Ward.
Third Vice-President—Dr. H. Taylor.
Corresponding Secretary—Dr. William Elmer, Jr.
Recording Secretary—Dr. William Pierson.
Treasurer—Dr. W. W. S. Phillips.
Standing Committee—Drs. T. J. Smith, E. J. Marsh, and D. C. English.

The next annual meeting will be held at Spring Lake, N. J., on the second Tuesday of June, 1886.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, April 23, 1885.

A. S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DIARRHŒA AND DYSENTERY IN CHILDREN.

DR. NATHAN S. ROBERTS read the paper, and said it was his purpose to treat the subject only from a practical and clinical standpoint, and to present some conclusions arrived at after considerable observation of diarrhœa in children in the densely populated districts toward the lower part of the city. The large proportion of deaths from diarrhœa in children in New York and London, and also in other cities, showed the importance of the subject under consideration, especially at the present time, when the warm season is approaching.

In children under one year of age we might often look for the cause of the intestinal trouble in the ill state of health or habits of the mother or nurse, or in the faulty method of feeding. Often also the disease arose from cold and dampness. In children over one year of age, as a rule, the cause would be found to lie in dentition or errors of diet, such as allowing of too frequent eating, or the improper use of vegetables, unripe fruit, and other articles unsuitable to the age of the patient. Other causes were the influence of measles and other zymotic diseases, pneumonia, impure air, high temperature.

Dr. Roberts distinguished the diarrhœa of children as either simple, enteric, choleraic, or so-called cholera infantum, and mixed diarrhœa. These several forms were characterized by certain peculiarities of the dejecta, and it was important always to note the appearance, the frequency, the amount, the odor, the chemical reaction, etc., of the passages. In the first form there was a simple diarrhœal discharge. In the enteric form the discharges were similar, but contained a considerable proportion of undigested food, pointing to imperfect digestion. In the choleraic the passages were thin, and squirted from the anus as from a syringe; they had not the normal acid reaction, but were alkaline and usually fetid. In the mixed form the passages contained considerable mucus, were sometimes streaked with blood, and attended by pain.

Treatment.—In this disease no temporizing or expectant treatment was admissible. Prompt and efficient treatment was urgently demanded, especially in the hot summer months, during the prevalence of cholera infantum. We should take into consideration all the hygienic conditions surrounding the case, and, if necessary, remove the patient to a better atmosphere. Cleanliness of the skin and proper clothing must be insisted upon, and most important was it that the dietary should be inquired into and regulated. Such food should be prescribed and in quantities and at intervals to suit the age and tastes of the patient. The author felt convinced that bad methods of feeding were responsible more than any other preventable cause for the presence of summer diarrhœa.

The subject of dietetics in children was a great one, and might well occupy our attention the entire evening, but it could only be briefly considered on the present occasion. If the mother would not, or could not, nurse the infant, it was better to provide a wet-nurse. If a wet-nurse could not be obtained, how should the baby be fed? The reply was that milk was the only suitable food for young infants. He should recommend that it be diluted with from one-half to one-fifth part of water for infants under a year old, and to add to each pint as much as fifteen grains or half a teaspoonful of soda, thus neutralizing acidity and preventing hard coagulum of caseine; or a tablespoonful or two of lime-water might be employed as an antacid. It was well to instruct the mother to test the milk with litmus-paper, and let that be a guide as to the quantity of the antacid to be added. If there be weak digestion add from five to ten grains of pancreatine dissolved in a little water; or the milk might be allowed to become digested for half an hour to three-quarters of an hour with pepsin, keeping the temperature at about 100° F., and then strain through a fine sieve, and give the whey with or without a portion of the finely divided curd. He preferred milk-sugar to cane-sugar for sweetening. In some cases of diarrhœa, attended by vomiting, he had found the white of an egg diffused in water a nutritious drink.

If the milk supply was questionable and did not agree with the digestive organs, then the artificial foods would have to be tried. First, if cow's milk disagreed, he would try condensed milk. Of the farinaceous foods for children past the third or fourth month, he had found Nestle's milk food as good as any. After the seventh or eighth month such food might be given as the child was best able to digest. In his experience young children did not take kindly to scraped meat.

As to the medicinal treatment in diarrhœa, one should carefully note the changes produced in the symptoms, and make frequent visits in order to keep careful watch of the case. In the selection of remedies we should be governed largely by the characteristics of the stools. In the simple forms of diarrhœa a few doses of gray powder will often be the only remedy required, but its administration should not be long continued. This was also true of other mercurial preparations in diarrhœa and dysentery; their continuous administration would end in prostration and anæmia, especially so in scrofulous children. Calomel in small and frequent doses was useful in so-called white or chylous diarrhœa, and drop doses of the tincture of nux vomica might also be useful. In case of greenish stools ipecac would prove useful. This medicine was employed largely in intestinal disorders, whether diarrhœal or dysenteric, in young and old persons. It seemed to induce normal action of the liver and bowels. In small doses it would often relieve nausea and irritability of the stomach. Small doses of rhubarb and soda, or teaspoonful doses of spiced syrup of rhubarb were well adapted to certain cases; where watery passages were attended with pain and sleeplessness, a few doses of Dover's powder, combined with bismuth, would be of advantage, but it was important to stop its use just at the right time.

The few remedies mentioned would often serve to bring the little patient safely through to complete recovery. Other cases, however, lingered on, even assuming a graver type of disease, the patient becoming prostrated from loss of vitality, the surface cold and clammy, the lips blue and the eyes sunken, etc. In these cases whiskey would often save the life of the patient. If we found the tongue red and dry, much restlessness, etc., the patient might be brought out of the condition by the administration of arsenic in one one-hundredth or two-hundredth grain doses. Veratrum album had been recom-

mended by Ellis in cases in which the nervous system was disturbed, and Dr. Roberts had found it useful not only in diarrhœas, but also in pneumonia and typhoid fever. The indications for its use in diarrhœa were great restlessness, heat, and frequent loose evacuations. In some subacute cases he had employed the spice pad, composed of powdered ginger, alspice, and cinnamon, wet with brandy or whiskey, and laid upon the abdomen. He had also used camphor-water in teaspoonful doses at the commencement of an attack with profuse loose stools.

Finally, in chronic cases search for a constitutional vice, and administer iron, quinine, hypophosphites, and other constitutional remedies.

Dysentery was so much more severe and dangerous than ordinary diarrhœa that it deserved separate consideration. It was a disease of the large intestine, and had its origin in dampness, cold, impure air, bad sanitary surroundings, such as were mentioned in speaking of the etiology of diarrhœa. It was preceded a day or two by malaise, symptoms of dyspepsia, the bowels acted more loosely than usual, and the passages became bloody and slimy, exceedingly frequent, accompanied by tormina and strain. Griping is not constant, but it usually precedes each act at defecation and is relieved thereby. The fever which usually accompanies the disease is often absent. The passages were usually offensive, and sometimes fine scybala were mingled with them. There was frequently prolapsus of the anus and vesical irritation; sometimes nausea and vomiting.

This disease could usually be brought under control in from six to seven days. It sometimes, however, proceeded to an atonic condition, with a frequent, small pulse, cold extremities, an anxious countenance, a dry tongue, and showed a strong tendency to terminate in death.

Active treatment should be adopted. The patient should be confined to bed, and the evacuations should take place in the recumbent position. Whiskey, opiates, and laxatives would suffice for the cure of the majority of cases, but success would depend largely upon their judicious employment. Various methods of treatment had been adopted by different authorities. If there were reason to believe that there was fæcal matter in the upper part of the intestinal tract, as was often the case, a dose of castor-oil with a few drops of laudanum was almost indispensable at the outset. Dr. West's prescription of castor-oil might be useful. Ipecac had been highly extolled by many, and Dr. Roberts felt certain it was of great value in many cases. He had found corrosive sublimate an excellent remedy in the dysentery of adults, but less reliable in children. To allay nausea and vomiting, he had sometimes given a few doses of creasote with most happy effects. If alcoholic stimulation were necessary he preferred pure whiskey, five drops to a teaspoonful, according to the age of the patient and the indications of the case.

After the violence of the disease had abated, in some cases convalescence would be slow, and here the pernitrate of iron was useful, together with nux vomica as a stomachic and nervine.

The most important general principles to be considered in the treatment of diarrhœa and dysentery were, first, to insist rigidly on compliance with hygienic rules; second, rest in bed until convalescence is thoroughly established, except so far as it may be necessary to vary from this rule to obtain better air; third, frequent visitation of the patient during the most critical stages of the disease; fourth, remedies employed to be administered as a rule in small and frequent doses, and discontinued when they have accomplished the special purpose for which they were indicated.

Dr. B. F. Dawson had had considerable experience with the treatment of the diarrhœa and dysentery of children some years ago, and had expressed some of his views in print. The paper read by Dr. Roberts left little to be said. Most of the gastro-intestinal disorders of children were due to improper feeding. Among the animal creation human beings were the only ones which were improperly fed and which suffered from diarrhœa and other intestinal disorders in consequence. Many of these disorders had been attributed to teething, but dentition was as natural a process as was the growth of the hair or nails, and should not give rise to disorder of the bowels. Even artificially fed children should not be exposed to diarrhœa and dysentery, or any of the pains said to accompany dentition. This view he regarded as not theoretical but practical, as he had witnessed that children when properly fed passed through infancy and childhood without diarrhœa or dysentery. When a child cried after taking food it meant pain, and the indication was to withhold food until the irritation had ceased. Instead of that, however, the mother or nurse gave the child more food, and added to the trouble, and thus the child acquired a diarrhœa. If the intestinal tract became irritated for any reason, causing loose fecal movements, as soon as the offending material had passed out, rest would lead to a cure. The mildest and the best medicine which we could then put into the child's stomach was pure cold water. If, however, continual bad feeding has led to a more marked degree of irritation, and some further treatment is necessary, he would not give opiates, but antacids and remedies which aid digestion. Among these were bismuth and pepsin. In dysentery opium might assist in relieving pain, but it should not be given in diarrhœa due to the presence of undigested food in the intestine. Here absolute rest and cold water constituted the best mode of treatment. Dysentery could always be traced in children to a previous diarrhœa; he had never seen a case of dysentery in a child in which the symptoms were those of dysentery from the onset of the disease. Inasmuch as it followed a diarrhœa, it indicated the importance of early recognition of diarrhœa and proper diet.

Regarding the elevation of the temperature, he thought that in itself it was not an important factor. The trouble was that the vessel in which the milk was kept was dirty, the surroundings were dirty, the air was foul, the child was not kept clean, it was fed too often, and the quantity of food was not reduced in hot weather. Intemperate and diseased mothers should not be allowed to nurse their children. It was perfectly easy to raise a child artificially fed. Instead, however, of feeding it with watered milk, he let the water settle to the bottom and gave the child the top of the milk. Give milk which contains plenty of fat or that which contains the largest proportion of cream. Indeed, instead of diluting milk, he added to it fatty material, either oatmeal or a little butter. He thought it a mistake to take the caseine out of the milk. What was desirable was to prevent a hard coagulum, and to secure this result nothing was better than to add barley or oatmeal-water to the milk, say one part of oatmeal-water to two parts of good fresh milk, and add a tablespoonful of lime-water and a lump of sugar. Observe the rule that a child should not be fed oftener than once in three or four hours. Dr. Dawson explained later that by barley and oatmeal-water he meant the gruel strained, the coarser part removed.

Dr. J. Blake White accepted the views expressed by the author regarding artificial foods, and said that nothing could act as a substitute for milk. He preferred, however, fresh condensed milk, properly diluted, to the fresh cow's milk. Many children fed on cow's milk suffered from diarrhœa and other affections because of the impurity of the milk or the source from which it came. A fault of what was considered the freshest milk which could be obtained for children in the city was that it came from cows kept closely housed and fed on slops, and such milk was uniformly acid.

He differed from Dr. Dawson regarding the influence of dentition in some cases, for it at times certainly caused intestinal disorders, and it might be necessary even to

lance the inflamed gums. Cool fluids were of advantage, as was also bismuth, lactopeptin, etc.

Dr. J. E. Winters thought he could add but little to what had been said by the author and the gentlemen who had discussed the paper. He disagreed with Dr. Dawson regarding the influence of dentition, for it undoubtedly did often cause disturbance of the alimentary canal in children. It was during the time of dentition that diarrhœa and dysentery most frequently occurred. There were also other reasons for the intestinal irritation, consisting in improper food, unusual functional activity of the intestinal tract from rapid development, etc. He thought, however, that the influence of dentition in producing diarrhœa had been overestimated, but still it should not be entirely ignored.

He heartily concurred in the opinion expressed by Dr. Dawson, that dietetics were the chief cause of indigestion and intestinal derangement in children. It occurred usually during the first eighteen months of life, and during that time children were usually milk-feeders, and milk was more liable than other forms of food to be contaminated and to ferment. But there was nothing which would take the place of cow's milk except the mother's breast. Infant foods were not as good as cow's milk for infants. He thought too much water was fed with the milk, and too little cream. Caseine in the quantity in which it existed in cow's milk was not readily digested by children, and he would allow it to gravitate to the bottom and give the top part of the milk, the cream. If milk were rendered alkaline and gruel be added it would prevent the running together of the caseine. He would not have a child nourished by a wet-nurse until other means had been tried. Many children grew up to be perfectly healthy while fed exclusively by the bottle.

Hot weather alone seemed to have less influence in causing diarrhœa than moisture of the atmosphere or electrical disturbances.

One point in the treatment, he thought, had not been sufficiently dwelt upon, and that related to the condition of the skin. The child should be kept cool, having almost no clothing during the summer months, and it should be frequently bathed.

Dr. L. E. Holt agreed with what had been said regarding prevention. The regulation of the diet was most important in prophylaxis. An important matter in the administration of drugs was, as had been stated by the author, to give them in small quantities frequently repeated. If they were administered in considerable quantity every three hours harm might result. He had come to rely upon opium more than upon any other drug in the diarrhœa and dysentery of children. It should be given frequently, its effects carefully watched, and if these points were observed it would not cause any cerebral symptoms. Next to opium one of the most valuable remedies was bismuth, given as frequently as every half hour or hour. If vomiting were present he used kumyss. He also bore testimony to the advantage of frequent bathing, and the administration of certain other drugs.

Dr. H. D. Chapin spoke of one point, namely, the influence of heat in the production of diarrhœal diseases in children. That the heat of summer had some effect in the causation of the disease seemed to be evident from the fact that the death-rate, as shown by the statistics at the office of the Board of Health, was much greater in July, 1882 and 1883, than during August of the same years, the average temperature for July being greater than during August. This fact pointed also to the importance of bathing, and he advised that children be allowed to play in the bath half an hour or an hour.

Dr. Dawson asked if the increased death-rate during the hotter month might not be due to over-feeding rather than to increased heat; although the child ate the same amount at all times, it required less during the hot months, but the mother failed to reduce the quantity of the food, or to give that which was less heating.

Dr. Fanning called attention to a recent article by Ringer on the use of mercury in diarrhœa, the indications for its administration being based upon the character of the stools.

Dr. Neal had found benefit from the use of the aromatics in the diarrhœas of children. He was more in favor of vegetable astringents than of minerals in the treatment of these diseases of young children.

Dr. John C. Peters favored a milk-diet for children, but the milk was often acid. There could be no cast-iron rule regarding the dilution of condensed milk. The quantity of water to be added could only be determined by a few days' trial. He had found that it was not hot air that caused the trouble in children, but hot foul air; the hotter the air, usually the fouler it became in cities. He was a little old-fashioned in his views as to the influence of dentition; he believed it sometimes caused intestinal irritation, and he sometimes lanced the gums. Regarding the frequency of nursing, during the first month the child should not nurse oftener than once in two hours, and the interval should be gradually lengthened to four hours. Night-nursing should be dropped as soon as possible, usually at the fourth or fifth month. He favored bathing and allowing the child to play in the bath; also sometimes used injections of tepid water, and applied a cold pad over the abdomen. He administered large doses of bismuth which contained no arsenic or other impurity.

Dr. A. C. Post thought too much stress could not be laid upon the evil influence of great frequency of alimentation. The mother or nurse should know that the child often cried during hot weather because it was thirsty, and not because it was hungry, and it should be allowed to drink of pure water; feeding or nursing should not take place oftener than every two hours during the first month, and not oftener than once in from three to four hours as the child grew older.

Dentition had been spoken of as a physiological process, and *a priori* it was claimed that it should therefore be painless and unattended by any irritation. But it was also true that menstruation, child-bearing, the evacuation of the bowels, etc., were physiological processes, yet we knew that they were often attended by pain and derangement of the health. There was no fact in medicine more clear than that dentition was sometimes exceedingly painful, and he had known children in whom the great irritation continued for hours and even days, and relief had been instantly afforded by lancing the gums.

Allusion had been made to the use of bichloride of mercury in the treatment of diarrhœa and dysentery, and he had found it a very valuable remedy. Let a grain be dissolved in water and a teaspoonful be given with the milk each time the child is fed. It also had an antifermentative effect upon milk. He had also derived benefit from minute doses of calomel. Where there was fermentation in the bowels, with pain and griping, charcoal would give prompter relief than any form of opium.

The President spoke of what might be considered as large doses of bismuth. He gave even twenty or thirty grains to a child a year old. He asked if allowing the child to nurse every two hours, even during the first month, was not too frequent; the stomach had not time to digest the first quantity before a second was taken.

Dr. Jacobus thought diet had a great deal to do with the production of gastro-intestinal disorders in children, and heat had a great deal to do with rendering the diet impure. Cow's milk as it came from the country was not fed to children before it was twenty-four or thirty-six hours old, and of course it was diluted more or less, the milk-cans were dirty, etc. That from cows kept in the city was faulty as being from cows slop-fed, etc., and it was therefore watery and acid. Among poor people the mother drank often of tea, causing, besides trouble with the bowels, also eczema. Ceasing the tea, the diarrhœal and eczematous trouble disappeared in the child. He preferred bismuth to almost all other remedies for the treatment of the diarrhœa of children. Regarding condensed

milk, he had found that children who had appeared to thrive on it during the first year, were not really strong; were soft and fat, and liable to succumb to disease during the second year. Bathing was one of the best means of reducing the temperature.

Dr. H. J. Boldt thought that bismuth did good only in cases in which there was acidity of the stomach, and that very large doses—from thirty to forty grains—were unnecessary and liable to produce irritation.

Dr. Billington, in reply to a question by the President, said he thought the general opinion expressed regarding the length of the interval between the taking of food by infants was well based; a positive rule, however, could hardly be adhered to under all circumstances. He expressed a preference for wet-nursing rather than for artificial feeding.

Dr. Roberts, in closing the discussion, said that when the child was raised on the bottle there should be a number of bottles at hand, and black-rubber should be used.

On motion, the Society adjourned to meet the fourth Thursday in September next.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ARTIFICIAL PRODUCTION OF CHOREA—DISCUSSION ON CHOREA AT THE MEDICAL AND CHIRURGICAL SOCIETY—OPINIONS OF DRS. ANGEL MONEY, HUGHLINGS JACKSON, TURNER, STURGES, HARLEY, AND BROADBENT.

London, May 30, 1885.

With the approach of the summer the medical societies are concluding their labors. The Medical, Clinical, and Pathological Societies have all closed for the present session. Before next month is out the rest will have followed suit. The Medical and Chirurgical Society still meets. At the last meeting great interest was evinced in a paper read by Dr. Angel Money, entitled, "The Experimental Production of Chorea." The meeting was actually prolonged half an hour beyond the usual time so as to give time for the discussion. The method adopted by Dr. Money was to produce capillary emboli by injecting a particulate fluid into an artery—generally the common carotid. Arrowroot, starch granules, and carmine were found to act best as emboli. The animals experimented on were rabbits, guinea-pigs, cats, dogs, and monkeys. No results had been obtained with the latter animals as yet. In the other animals capillary embolisms of the brain and upper part of the spinal cord had occurred, and in many cases involuntary movements had been produced indistinguishable from chorea. Dr. Money said the "chorea" never followed capillary cerebral emboli but only ensued on capillary embolism of the spinal cord. In nearly every case, however, in which the brain was affected with capillary embolism, some form of "involuntary movement" was present. The want of development of the pyramidal tracts in the animals under consideration possibly explained why chorea did not in them result from embolism of the brain proper. The author maintained that the reasons for locating the lesion in the brain in most cases of human chorea were too powerful to be upset by experiments on animals so far removed from man. When the artificial "chorea" was well marked, reflex action in the cord was exaggerated. Dr. Money suggested that in those few cases of human chorea in which the reflexes are exaggerated, the spinal cord will be found to be the seat of the disease.

An interesting discussion on the general pathology of chorea followed the reading of the paper, but the exigencies of space forbid my noting more than a few of the most salient points.

Dr. Hughlings Jackson remarked that Dr. Money's researches had proved that involuntary movements can be produced by artificial embolism. We could not expect to see movements in a dog's forelegs like those of a child's arm in chorea. The dog was not capable of such elaborate movements. The elaborateness of the movements in human chorea pointed to the lesion being "high up" where the nervous arrangements are complex. As the face is affected in chorea, the lesion must be above the cord. Cases of hemichorea in which the face is affected were inexplicable on the view that the lesion was only spinal. Certainly cases of pre- and post-hemiplegic chorea were inexplicable on that view. Dr. Hughlings Jackson said it was objected to the hypotheses of embolism and thrombosis that these processes lead to destruction of nervous tissue. That was true, and, of course, from destroyed nerve-tissue no movements of any sort could result. But it was equally true that with destructive lesions there sometimes occurred over-development of movements, *e.g.*, post-hemiplegic chorea; also epileptiform seizures occurred in some cases of local cerebral softening from thrombosis or embolism. A condition for repeated seizures was established. In these, and in most cases of chorea, we had two opposite states to account for, some paralysis and some over-movement. Destruction of some nervous elements from embolism could only account for the paralysis in chorea. There must be over-activity of some other nervous elements to account for the coexisting exaggerated movements. Dr. Jackson said he reasserted that movements of some kind (post-hemiplegic chorea, athetosis, epileptiform seizures) do occur in cases where there are destructive cerebral lesions.

Dr. Charlewood Turner thought the embolic theory scarcely sufficed to explain the phenomena of chorea, because the effects of capillary embolism soon passed away. Where emboli caused permanent destruction, paralysis ensued.

Dr. Octavius Sturges opposed the embolic theory. He said a febrile attack, *e.g.*, tonsillitis, would stop chorea. An acute specific fever, such as scarlatina or typhoid, would abolish chorea, and the chorea would not, so far as he knew, return on recovery from the fever. In chorea the sexes were so differently affected and so were different races. Again, emboli were absent in fatal cases occurring in children.

Dr. Cobbold drew attention to the various irregular nervous movements which occurred in horses the subjects of "worm" aneurism, the movements resulting from the introduction of these worms into the arterial circulation.

Dr. John Harley said he had shown cryptopia could cause choreic movements.

Dr. Broadbent said he thought age rather than race and sex was the most important factor in human chorea. He had held that capillary embolism was one cause, but by no means the sole cause of chorea. Dr. Money had shown that almost every symptom of nervous lesions could be caused by capillary embolism. The movements in animals were not the equivalent of chorea in the child. Human chorea was distinctly a cerebral affection, as the cases of hemichorea also proved. Dr. Broadbent said he had more than once seen hemichorea followed by paralysis and reappear as the paralysis disappeared. Among febrile affections, scarlatina generally did away with chorea; typhoid did not, as a rule; other pyrexia, in his experience, affected it but little.

Dr. Angel Money, in replying, said he had nowhere in his paper contended that human chorea had ever been caused by capillary embolism. He had only gone so far as to say that, in some animals, some irregular movements, which appeared to him indistinguishable from chorea, had been produced in this way. He considered capillary embolism to be only one of the causes of irregular movements in animals. Chorea in the human subject had, he considered, many causes; in a few cases cerebral embolism might be the origin. As to the action of fevers upon chorea, he had seen typhoid both annul and produce it.

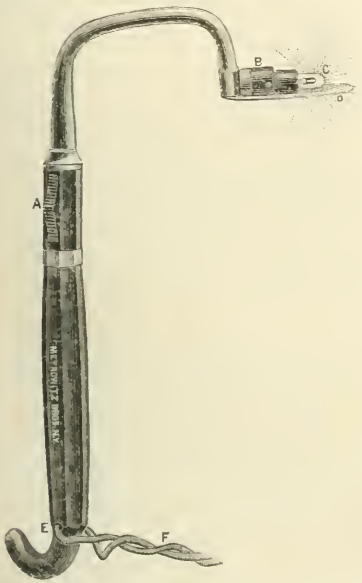
New Instruments.

DR. BLEYER'S MODIFICATION OF TÜRCK'S TONGUE-DEPRESSOR, WITH ELECTRIC LIGHT ATTACHMENT.

By J. MOUNT BLEYER, M.D.,

NEW YORK.

I HAVE had in use for months a modified Türck's tongue-depressor, which I have found gives such satisfaction that I feel justified in bringing it before the profession. An illustration is herewith given. It is believed to



A, Interrupting handle; B, socket for the incandescent lamp and connection with the handle; C, incandescent lamp; D, tongue-depressor; E, connection cord with handle; F, cord connection with battery.

be an improvement upon all tongue-depressors at present in use. The incandescent lamp attachment makes it a valuable instrument from a clinical point of view. The principle for using the instrument is essentially the same, but its application, as compared with the former tongue-depressors, is much wider, and its construction is simple and uncomplicated.

It will be found greatly to facilitate the management of light, and especially is it valuable for use at the bedside, where gas or reflected light is not at hand.

Students and physicians often expend unnecessary time and trouble in managing reflected light, and an instrument so arranged as to reflect light without mirror, lens, and other objects, is certainly an improvement.

The simplicity of construction of this instrument will be obvious from an inspection of the cut, and I have only to add that it has been my aim to place all connecting wires in such a way as to render it absolutely antiseptic.

In regard to batteries suitable for the purpose, at present there are few in the market which I can recommend.

The Storage Portable Battery, to which the instrument is attached, is specially designed for physicians and surgeons. This battery runs a half-candle lamp one hour, size $3\frac{1}{2} \times 1\frac{3}{4}$ inches; a half-candle lamp two and a half hours, size $3\frac{1}{2} \times 1\frac{1}{2} \times 1\frac{1}{2}$. The weight of this battery is from eight ounces to two pounds. It can also be made use of with constant or interrupted current apparatus, electric puncture-needles, and galvano-cautery.

For office use a good instrument is the magnetic motor machine manufactured by a company in this city. This machine may be placed from fifty to one hundred and fifty feet or more from the consulting-room, and wires drawn from thence connected to two posts, placed on a small table, wherewith the instrument may be illuminated. The same company manufactures a small battery, $6 \times 7\frac{1}{2}$ inches, for visiting purposes, which can be easily carried.

I have at present its allies in construction, viz., laryngoscope, nasal speculum, ear speculum, vaginal speculum, and rectum speculum, which have many advantages over those at present used by the profession.

This instrument is manufactured by Messrs. Meyrowitz Brothers, opticians, who have taken special care to insure all the requirements which I have mentioned, and which I deem essential in a good instrument, and who have also the batteries mentioned herein on exhibition.

67 EAST THIRD STREET.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 7, 1885, to June 13, 1885.

FRYER, B. E., Major and Surgeon. Ordinary leave of absence extended six months, from July 1, 1885, on surgeon's certificate of disability. S. O. 129, A. G. O., June 6, 1885.

The order directing Major P. J. A. CLEARY, Surgeon, to change station from Fort Union, N. M., to Fort Lyon, Col., is revoked. S. O. 81, Department of Missouri, June 8, 1885.

RICHARD, CHARLES, Captain and Assistant Surgeon. Granted leave of absence for three days. S. O. 128, A. G. O., June 5, 1885.

MACAULEY, C. N. B., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Sisseton, D. T., and ordered for duty at Fort A. Lincoln, D. T. S. O. 61, Department of Dakota, June 5, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 13, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
June 6, 1885	4	13	71	4	100	70	0	0
June 13, 1885	4	18	74	5	95	59	0	0
Deaths.								
June 6, 1885	1	3	16	3	12	26	0	0
June 13, 1885	0	4	11	5	7	20	0	0

ANOMALOUS LACTATION.—Dr. W. F. Morgan, of Leavenworth, Kan., writes: "The case of anomalous lactation reported in THE RECORD of May 23d calls to mind one in my own practice here in 1873. A mulatto woman, about sixty years of age, was in the habit of putting her grandchild to her breast to quiet it at night, and in a few days was astonished to find that the baby had very substantial reasons for seeming satisfied with this plan, as it had excited a free flow of milk to breasts that had been dry for fifteen years."

Blond Hair and Exophthalmic Goitre.—Dr. J. C. Neal, of Archer, Fla., writes: "In all the cases of exophthalmic goitre I have seen for several years, the patients, mostly female, have had auburn hair. Is this a coincidence or not? Have others noticed such cases?"

The Herb Doctor's Paradise.—Consul Wright, of Santos, Brazil, encloses in a letter to the State Department notes upon the medicinal plants of that country. The compilation is the work of S. S. Schindler, a native-born citizen of the United States, who is now in Brazil. From Mr. Schindler's notes it appears that the country abounds in herbal remedies, and that alvelos, the new cancer cure, is but one of hundreds of plants possessing properties of value, as yet almost unknown to materia medica. Alvelos is a shrub, Mr. Schindler writes, discovered by an eminent physician of Pernambuco to be a specific for cancerous ulcers. The juice is a powerful caustic. Applied to cancer, it produces an irritating effect, which increases to a strong inflammation, and at length cicatrization takes place. The manner of application is this: A camel's-hair brush is dipped in the juice, which is applied to the cancer and allowed to dry. Twenty-four hours afterward a little lint dipped in water is applied to the cancer, and in another twenty-four hours the juice of alvelos is tried again. Dr. Velloso advises for a speedy cure the application of the juice every day, using an infusion of tobacco instead of the arnica and water. This course of treatment is more rapid. The inflammation is much stronger, but can be regulated by the physician according to the nature of the cancer and its proximity to vital organs. Mr. Schindler says that the alvelos treatment has proven successful in every case of cancer of the lips, tongue, nose, and breasts where it has been tried. Baycuru, Mr. Schindler says, is a curious plant of Brazil, which buries itself in the sand, a number of leaves rising above, seven inches long by two inches wide. The flowers resemble a saxifrage. The whole plant is sometimes for days together covered by the sea. The root is six to seven inches long, one inch thick, and of tortuous shape. Externally it is chocolate brown; internally, flesh colored. It is an unfailing remedy in all kinds of enlargements and glandular swellings. The juice of the fruit of the cajueiro tree is one of the most powerful blood-purifiers known. A decoction from the bark of the root of the calunga shrub is a remedy for dyspepsia and intermittent fevers. The leaves of the camapa plant contain a narcotic principle, and the juice of the root and fruit is found excellent for rheumatism and liver diseases. Boiled fruit of the arvore do pao tree makes a powerful poultice for ulcers. The fruit of the cabacinho has an admirable effect upon dropsy. The most stubborn coughs yield to a tea made from leaves of the malvarisco shrubs. Papaw has been found to possess the property of destroying the false membranes of croup and diphtheria. Papaine is another diphtheria cure. Poracary is a sure antidote for bites of snakes. Sapucareira bark makes a decoction which seems to be nature's remedy for kidney ailments. There are no less than three hundred and twelve plants or trees in Brazil which possess strong medicinal properties. Mr. Schindler's catalogue of them contains a remedy for every ill known to human flesh, and the wonder inspired in the reader is that people should ever die in that country.

The English Substitute for Chloroform.—Mr. Braine, who is a professional anæsthetist, says that in England, of late years, the place of chloroform has been chiefly taken by the A. C. E. mixture, which is equally portable with chloroform, and can be used in almost all the cases in which an anæsthetic is required. "For obstetric operations, and in dental cases in children, I generally use it. In fact, armed with a bottle filled with A. C. E., an anæsthetist is equal to most of the emergencies of his practice, and probably possesses an agent more nearly universally capable of application, with almost complete safety, than any other anæsthetic compound. The chief objection to it, perhaps is that it is somewhat slow in producing entire anæsthesia. Wherever practicable, it should be used rather than chloroform. The exhilarating effects of the three parts of ether seem to more than antagonize the depressing effects of the two parts of chloroform, so that scarcely any deaths, if any, have been reported from its use. Should syncope occur during its administration, the same measures as are recommended for such an emergency from chloroform should be adopted. But, in spite of this strong testimony in favor of A. C. E., I am yet of opinion that, of all the compounds hitherto employed for the production of anæsthesia, none other is equal in safety to nitrous oxide gas for short operations, or to the gas combined with ether, for longer cases."

Syphilis and Æsthetics.—The following flight of medical fancy from the *Columbus Medical Journal* will hardly be relished by Italian patriots: "As the fires of the Infernal had found an expression for their invisible forms through the soul of Dante, one of the most classic and beautiful of bards, so syphilis sought its darkest expression in his native land, unrivalled in the beauty of her classic wealth. This is no breach of consistency. Out of one extremity is born its counter-extreme—and among the *contras* to that extremity of æstheticism which once gave to Italy her fairest title to worth, must be classed the syphilis for which she served as an unhappy nidus."

The Safety of Nitrous Oxide.—Mr. Braine, in the *British Medical Journal*, says: "Pregnant women, even as far advanced as eight months, take nitrous oxide well. I may here mention the case of two patients, who were suckling, and in whom the shock from the extraction of a tooth, without the gas, stopped the secretion of milk; subsequently, having to undergo a similar operation, under like circumstances, they determined to take the gas, and in neither instance did any derangement of the functions of lactation occur. Great age is no bar to the administration of nitrous oxide; my oldest patient, a lady, having reached the age of ninety-four."

Failure of Pelletierine.—Dr. W. A. Miner, of Mount Kisco, N. Y., sends us the details of a case in which pelletierine entirely failed to cause the expulsion of a tape-worm. The patient was a gentleman, who had been passing segments of the worm daily. He was twice treated with the new drug, careful directions being given as to fasting and cathartics. Some large pieces were expelled, but the head remained. The medicine is expensive; it caused dizziness and cramps in the legs; it failed to cure, hence our correspondent thinks less highly of the new remedy. We would state that pomegranate has been found to expel the worm in 54 out of 134 cases, or forty-three per cent. Pelletierine has succeeded in seventy-six per cent. of cases. There is apparently no specific for tape-worm, but pelletierine is probably one of the best remedies.

Voluntary Acceleration of the Heart.—Dr. Tarchanoff has recently reported the case of a young medical student who has the power of accelerating the beat of his heart at will. The volitional impulse seems to act upon the accelerator nerves of the heart rather than on the vagus.

A Simple Treatment for Burns.—Dr. Squibb, in *The Ephemeris*, remarks that the officinal aqua creasoti, or creasote water, a simple one per cent. solution of wood creasote in water, is, like similar solutions of carbolic acid and of cresol, a most effective local anæsthetic and topical dressing to burns and scalds. It is no better than the solutions of carbolic acid, or of coal-tar creasote, for this purpose, but it is quite as good, so that whichever is most accessible or most convenient may be used.

Vol. 27, No. 26 NEW YORK, JUNE 27, 1885 Whole No. 764

Original Lectures.

ENURESIS, OR INCONTINENCE OF URINE.

By ALEXANDER W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL (GENITO-URINARY DIVISION); PROFESSOR OF VISCERAL ANATOMY AND PHYSIOLOGY, NEW YORK COLLEGE OF DENTISTRY; PROFESSOR OF COMPARATIVE PHYSIOLOGY, AMERICAN VETERINARY COLLEGE, ETC., NEW YORK.

THE study of enuresis, or incontinence of urine, leads unavoidably to the consideration of some points in the physiology of the bladder; and while we cannot at present enter into the details of this subject, introductory to our theme two leading and important questions suggest themselves: First, to what extent is the function of the bladder dependent upon cerebral, spinal, or sympathetic action? and, second, in this action, how much is to be allotted to exciting, automatic, and inhibitory influences?

As we can intelligently answer these questions, so will be our understanding and solution of the various physiological and pathological problems which the bladder constantly presents to us.

At first sight, the evacuation of the bladder would seem to be wholly a voluntary act; indeed, it is by many so regarded. It is an indisputable fact that the bladder is, in great part, under the control of volition. No one will deny that its evacuation may be restrained or promoted, according to will. The voluntary relaxation of the urethral muscles as preliminary to the flow of urine; the power we possess of suddenly arresting the flow before complete evacuation has occurred; the power which we are at times called upon to exercise of deferring the act of micturition, though the bladder may be in an uncomfortable state of distention—these, together with the influence which the brain indirectly exercises on the movements of the viscus itself, as shown by faradization of the crura cerebri and restiform tracts, are sufficient evidences of the controlling influence of the mind upon the bladder function. But we observe that this power is exercised more upon the surrounding media than upon the bladder itself. And, after all, it is a limited power we thus possess; we may reinforce excito-motor reflexion by voluntary effort upon the striated urethral muscles for a time, but only for a short time, after which the reflex impulse to evacuation becomes too urgent to be resisted. This is notably the case when the sensibility of the vesical mucous membrane is from some cause augmented (irritability, inflammation, etc.). If we examine the subject more closely, we are forced to the conclusion that the accumulation and discharge of urine is effected more through involuntary than voluntary agency. It is a matter of common experience that perfect micturition may take place independently of the will or of consciousness. We have not only abundant clinical evidence of this fact, but experiments in this direction are also very conclusive. After section of the cord in dogs between the dorsal and lumbar regions, by which of necessity both sensory and volitional impulses are interrupted between the brain and bladder, the animals do not suffer with retention, but micturate perfectly at stated intervals and in large quantities. It has been observed in these instances that when the bladder is full, micturition often occurs spontaneously, or it requires but slight peripheral stimulus, such as "sponging the anus," or "elevating the animal from the recumbent posture by the forelegs," to bring it about. Thus, micturition as an involuntary act explains why peripheral irritation enters so largely in the causation of incontinence. But it is not necessary that the afferent impulses should proceed from the peripheral nerve-endings; they may originate in the brain—an idea, simple or emotional, may inhibit or exalt the micturition centre of the cord, and thus cause either incontinence or retention. That many men are unable to pass water in the presence of strangers who watch them; that some persons cannot approach a running stream without having an irresistible desire to micturate; the strong impulse of the student to empty his bladder before entering the "green-room;" the difficulty experienced by a novice to make water while in a moving wagon, an act easy enough for one who is accustomed to it,[1] and many more odd and hitherto unexplained phenomena which the bladder constantly exhibits both in health and disease, can, I think, be sufficiently accounted for in the inhibitory or exalting influence which cerebral operations exert upon the spinal centre governing the bladder. The motorial impulse which originates in the brain, and by which the bladder is animated to contraction, does not pass uninterruptedly or directly to the bladder. We have no evidence of such an arrangement; the volitional impulse descends the cord to a certain segment or centre of nerve-cells, whose molecular machinery it sets into action. Thus micturition, a complex act, is essentially reflex in its mechanism, whether the afferent impulse proceeds from the peripheral ending of nerves or descends from the brain.

Incontinence of urine is a common ailment of childhood. It is often met with in the aged, and less frequently during middle age. At these various periods of life, however, it has a different signification as regards etiology.

The causes of incontinence may be classified into mechanical, anatomical, neurotic (peripheral and central irritation), local (irritability of bladder, inflammation, etc.), traumatic (extreme dilatation or laceration of female urethra, cystotomy, etc.), and idiopathic.

The mechanical causes may be divided into: 1, Those operating within the urethra and bladder; 2, those operating external to the bladder. Under the first heading are those causes which induce an imperfect closure of the vesical neck, as occurs when the median portion of an hypertrophied prostate separates its lateral lobes and, acting as a wedge between them, renders the vesical orifice more or less patent. In like manner impaction of a calculus at the vesical neck gags the orifice, prevents complete closure, and causes trickling by the side of the stone.

Stricture of the urethra, when of long standing and deeply seated, may affect the sphincter power of the bladder. Traumatic perineal strictures especially tend, by thickening and induration, to encroach upon the muscular element of the membranous urethra, and interfere with the natural function of this part. Again, in consequence of the undue effort which the bladder is obliged to make to propel its contents through the obstruction, a dilatation or pouch, sometimes of considerable dimensions, forms behind the constricted part, forming, as it were, an accessory reservoir for the accumulation of urine, which dribbles away after the bladder has closed. This sort of incontinence is not at all uncommon with old strictures, and, as these post-strictural pouches or

[1] I know a gentleman, aged about forty, with no trouble with his urinary apparatus, who cannot pass water while on shipboard. During a trip to Europe he was obliged to resort to the catheter exclusively, both going and coming.

dilatation, are situated usually in the membranous and prostatic portions of the canal, they in time impair the physiological integrity of the external sphincter, enfeebling and rendering it incapable of resisting even a moderate hydrostatic pressure, and thus the individual is obliged to yield at once to the desire which comes upon him, or he is overtaken before he can help himself. Again, it is important to constantly bear in mind that an involuntary flow of urine in the adult often indicates primarily a retention of urine, not incontinence. Given an inordinately distended bladder, the prolonged and constantly increasing hydrostatic pressure overcomes the sphincter-power and passive overflow occurs. Hence, in all cases of involuntary flow of urine in the adult, we instinctively palpate the abdomen for the recognition of this cause. Among the causes operating externally are the various uterine displacements, abdominal and pelvic tumors, etc., which, by pressure, compromise and irritate the bladder to undue functional activity.[1] A contracted bladder or a concentric hypertrophy of its muscular coat is a common factor not only in the causation of "irritability," but of incontinence. As an anatomical cause atrophy of the sphincter is not uncommon with the aged, which may create a weakness varying in degree from a partial to a complete loss of retentive power. Atrophy and fatty degeneration may involve both detrusor and sphincter, and as one or the other set of fibres are mostly affected we shall have retention or incontinence predominating.

In the adjoining ward is a man whose sole complaint, aside from general feebleness, is difficulty in holding his water for any length of time. His stream is weak, but he micturates very often during the day and several times at night. He finds some difficulty in starting his urine, but when once the stream has commenced he is unable to withhold it. The impairment of his sphincter power is evident in the frequent micturition and his inability to arrest the stream once commenced, while textural change in the detrusor is manifest in the enfeebled expulsive action. The catheter does not detect residual urine, but in view of the pathogenetic changes that have already taken place in the detrusor he will now be taught the self-use of the catheter, and warned to see that complete evacuation of the bladder occurs, to avoid further and more serious trouble in the future.

My experience is that, after puberty, incontinence prevails more frequently in females than in males. Especially in those who have borne children, an enfeebled condition of the sphincter is often manifest. I have in mind several women in whom the slightest exertion, such as laughing, coughing, or sneezing, causes an escape of urine. With some this trouble has existed for years, with others it appears after each parturition and remains perhaps a few weeks. The suggestion is quite probable that in these cases the infirmity depends upon a paresis of the sphincter induced by extreme pressure of the fœtal head in delivery.

You are aware that from the same cause—undue or prolonged pressure—sloughing of the vesico-vaginal septum sometimes occurs, with the formation of fistula and constant dribbling as the consequence. But it is suggested[2] that the slough may not involve the whole thickness of the vesico-vaginal septum, but yet go deep enough to include a portion of the sphincter fibres in the destructive process, or else the healing of the vaginal slough corresponding *in situ* to the vesical neck may by subsequent cicatricial contraction act mechanically in drawing upon and preventing firm apposition of the vesical neck. The baneful effect of traction on the vesical neck is further illustrated in the case of a child three years old related by Estrada.[3] The labia were united and had sealed up completely the orifice of the vagina, leaving, however, the meatus urinarius free. The labia having been divided by a bistoury, it was found that the hymen consisted of intercrossing muscular fibres extending from below upward in such a manner as to draw the urethra downward and produce incontinence. The treatment, which was perfectly successful, consisted in dividing the parts freely and fastening them back with sutures to prevent reapposition.

One of the most common causes of the trouble is the existence of some peripheral irritation. In order to appreciate the rationale of this cause in the induction of incontinence we have but to call to mind the fact already mentioned, that micturition is essentially a reflex phenomenon, and that observation and experimentation clearly demonstrate the influence of peripheral stimuli in effecting a perfect act of micturition. In view of these facts we can readily perceive how easily any irritation existing in parts presided over by the same nerve-centre may produce the trouble in question. Thus phimosis, in retaining the secretions around the glans penis and preventing cleanliness and the adhesions which frequently result between the preputial mucous membrane and the glans, is a most common cause of incontinence. In many boys a very moderate degree of phimosis will be sufficient to cause incontinence. There may be an excessive length of prepuce with but little contraction of orifice, or there may be but slight elongation with considerable contraction, insufficiency of meatus, ascarides, hemorrhoids, fissure of anus. In women granular disease of the cervix uteri, vascular growths (carunculæ) at or in the neighborhood of the urethra are frequent sources of peripheral irritation.

Among the numerous central nervous disturbances that occasion this trouble, epilepsy, hysteria, and chorea are among the most common. A boy at present under my observation, who has had convulsions more than ten years, presents the peculiarity that he invariably wets the bed the night preceding a fit in the early part of the day. He never has incontinence at any other time, and this has now happened so often, that no matter how well he may seem when he awakes, we look upon the wet bed as a premonitory sign and ply him with bromide and chloral.

But there are many cases of incontinence of children in which we can discover no pathogenetic factor whatever to account for the trouble, and in which we seek in vain for any peripheral or reflex cause. These cases belong to a class by themselves and have purely an anatomico-physiological basis for their causation. If the harmony of action between the retentive and expulsive forces of the bladder are in any way disturbed, retention or incontinence will inevitably follow, and in the idiopathic incontinence of children it may be assumed that there is either an anatomical disproportion between the retentive and expulsive factors, or else there exists an inharmonious nervous action. In other words, the incontinence may depend upon the operation of a powerful detrusor against a feeble sphincter, a condition which is the normal relationship of these parts in infantile life, or else there may be a disturbed or unequal neurotic action, the detrusor being in a condition of exalted sensibility or excitability, while the sphincter is in a condition of deficient innervation. A nice point to decide is which of these conditions prevails in a given case, and both factors may play their part simultaneously. The anatomical disproportion of the sphincter to the detrusor in young children is so well known that this has always been regarded as an element in the causation of incontinence, but this cannot be the sole or even the first cause of the complaint, because often enough the malady is intermittent; children will suddenly cease wetting the bed for quite an interval at a time, and if the cause was simply one of deficient muscular development, this would not obtain. Also the remarkable effect of perhaps a single application of the faradic current, in permanently curing the malady, as experienced by Ultzmann and

[1] Stein, Alex. W., M.D.: Irritable Bladder, New York MEDICAL RECORD, May 16, 1885.
[2] Murray, R. Milne: Post-partem Incontinence of Urine, Edin. Med. Jour., April, 1881.
[3] London Medical Record, June 15, 1880.

others, is a therapeutic result which could only have been obtained in cases of deficient innervation perhaps, but not imperfect development of sphincter. We must not appear too wise about this matter; the fact is, our knowledge of the physiology of the bladder is too crude to enable us to explain the immediate cause of many cases of idiopathic incontinence, but we may assume that most commonly it is a neurosis, depending upon some temporary molecular disturbance of that segment of the cord which presides over and co-ordinates the movements of the bladder. It may be the disturbing influence comes to the micturition centre through peripheral nerves, in which case the involuntary flow is a purely excito-motor manifestation, it may be it comes by impulses from the encephalon, in which case it may be sensori-motor or even idio-motor, as when the child actually dreams that he is micturating against a wall or in the *pot de chambre* in the ordinary way.

Feeble, anæmic, badly nourished, scrofulous children are said to be most frequently the subjects of this infirmity, but this is by no means always the heritage of a feeble organization. Many such children are never affected with this trouble, while the healthy and robust often present the most obstinate forms of the complaint. The history as given is almost uniformly the same. The child empties his bladder, goes to bed, falls asleep, sleeping, perhaps, profoundly, and in a few hours wets the bed. Sometimes this occurs toward morning, when considerable urine has accumulated, sometimes soon after falling asleep, although the bladder was emptied just before going to bed. Some children will wet though they may be awakened two or three times during the night. Usually the sleep is profound, but this is not essential to nocturnal incontinence. Many children sleep so soundly that they may be undressed and moved about without waking, and they never wet, while others sleep lightly and yet they are habitual bed-pissers. Usually the wetting is effected unconsciously; sometimes there is a vague sense of the desire to micturate, the child dreams that he is urinating in a proper place and manner. The incontinence may be wholly nocturnal, but there is in these cases often some manifest weakness also by day, but now the passive contraction of the sphincter is supplemented and strengthened by cerebral influences which are in abeyance during sleep.

The incontinence of childhood is brought often enough to the attention of the physician, but it exists even more frequently than is generally supposed. Many parents regard the trouble as merely a nasty, lazy habit, which they do not care to speak of, especially as there is a popular belief that there is little to be done for it, aside from moral suasion and discipline, and they know that sooner or later they "grow out of it." It is quite impossible to say when the trouble begins. As I have already said, it would seem that in infantile life the expulsive and retentive powers of the bladder are not equally balanced, there is a deficient sphincter stimulus or resistance, the hydrostatic pressure required to overcome the sphincter is slight, and the child wets often; gradually, however, a proper harmony of action obtains between the expulsive and retentive forces, and usually before the second year the child has voluntary control of his bladder. If after this time he is unable to retain his urine we may assume that this harmony of action has not been established. a congenital weakness of the sphincter remains, and the child still suffers from incontinence. Thus idiopathic enuresis commences with infancy, and continues often until the eighth, ninth, and tenth, sometimes even to the seventeenth year. The trouble often terminates suddenly, or after a few relapses. Severe intercurrent disease, such as the acute exanthemata, have been known to arrest the incontinence temporarily, sometimes permanently. When the child has once clearly evinced his retentive power, and suffers from incontinence at a later period, it will be found to be due to some local or reflex cause and not to congenital weakness.

Success in the treatment of incontinence will depend upon the recognition of its cause. It is obviously illogical to direct treatment to a symptom whose exciting cause is still operative. In all cases, therefore, before internal medication is resorted to, we seek to ascertain the existence of some local or remote iritation, and we can afford to expend our energy in the recognition and removal of this, as further treatment will rarely be necessary. But there are cases, and not a few, which are not so readily disposed of. When the difficulty has existed from earliest childhood, as is so frequently the case, and continues without assignable cause, as is also often the case, it is more difficult of management than when it occurs at a later period of life. Some of these cases, let it be frankly confessed, baffle our best efforts, until a certain age is reached, when nature comes to the rescue and the evil terminates spontaneously, and if now we happen to have employed a new remedy or a new method of treatment, we are too apt to "lay the flattering unction to our souls" that the merit is ours, and hasten, perhaps, to publish the virtues of our "discovery." If we are to judge from the great variety of remedies that have been unsparingly vaunted in and out of print for the relief of this complaint, I am sure I do not draw inordinately on my imagination.

The methods of treatment may be classified into surgical, mechanical, and medical. Surgical treatment naturally includes all operations required for the removal of calculus, phimosis, adhesion of balano-preputial mucous membrane, enlargement of meatus, hemorrhoids, etc. At the same time let us be conservative in this respect, especially regarding circumcision. We are so impressed with the import of phimosis as a factor in the etiology of incontinence that a boy dare not confess having once "wet" without endangering his prepuce to amputation. I say this, because I have known circumcision performed so many times for the relief of incontinence, with scarcely a question, hesitation, or doubt as to the result, and with signal failure. The injunction of Dr. Landon Carter Gray[1] is, I think, here eminently fitting: "That in all cases of nervous disorders with accompanying genital irritation, we should not regard the latter as the cause of the former until all other probable, or even possible, causes have been rigidly excluded." The introduction of a bougie or sound every day, or every other day, is in some cases of decided benefit. Mechanical distention of the bladder by means of warm-water injections, repeated daily for a week or more, has been successfully resorted to, especially by Braxton Hicks (London), in the cases of several adult females. With the view of strengthening the sphincter power, and diminishing undue sensibility, the patient should be enjoined to hold water as long as possible during the day. In this connection may come up the question as to the propriety of waking the child at stated intervals during the night. Many insist upon this as an absolute necessity. So far as it prevents repletion of the bladder it would seem of service, but beyond this the importance of this precautionary measure has, I think, been much over-estimated. The degree of repletion of the bladder and incontinence do not necessarily stand in the relationship of cause and effect. Children with this infirmity will at times retain an astonishingly large quantity of urine, while again the bladder yields to the stimulus of a very small accumulation, and they will wet in spite of every precaution that may be taken to the contrary. I have now in mind a little fellow about nine years old, who is taken up at night, and, after much coaxing, perhaps threatening, on the part of the mother, and considerable effort on his own (in his partially roused state), to relax his sphincter, he passes a large quantity of water, much to the satisfaction of the mother, who congratulates herself that she has, in the nick of time, prevented a deluge, but as soon as the little fellow falls asleep he wets himself. This occurs almost invariably,

[1] Annals of Anatomy and Surgery, February, 1882.

and I have observed this peculiarity in several other instances. Many cases present in which there is no assignable cause, or in which, the exciting cause having been removed, the incontinence persists; simply from habit, a susceptibility is engendered on the part of the bladder to yield involuntarily to the stimulus of a small quantity of urine, and I question whether by calling upon the bladder to empty itself at stated periods, we do not promote this habit, and act inconsistently with our endeavor during the day to induce the bladder to retain its contents as long a time as possible. In regard to this question, a very important consideration is the fact, which I have often noted, that when children are taken up to micturate at night they are so imperfectly aroused that the evacuation of the bladder can scarcely be regarded as a voluntary act, and unless the child is thoroughly awakened and made to micturate with full consciousness and volition, I believe the practice does more harm that good.

The external application of the "essence of birch" is a favorite domestic remedy, and I have in mind at least two or three cases in which, I must confess, I saw it accomplish wonderful results, but these were instances in which the "weakness" was mostly diurnal and was largely due to negligence and bad habit. In the majority of cases, I believe with many, that the children are not responsible for this infirmity, and if psychical influences do not avail, if we cannot arouse their consciousness to the "filthy" habit, and appeal unavailingly to their sense of pride, etc., the slipper will rarely accomplish more.

The meatus and prepuce have been closed with collodion, and a variety of pads, elastic rings, clamps, and appliances have been devised for the purpose of mechanically preventing the escape of urine. Associated as some of these contrivances are with good names, yet it must be admitted that little ingenuity has been expended in their construction, and the philosophy on which they work is as feeble as the infirmity which they are supposed to correct. It is simply that in consequence of the impediment to the outflow of urine the child is wakened as soon as the sphincter relaxes. What possible good can we hope from this practice? What more is it, indeed, than a confession of ignorance, both as to the etiology and treatment of the complaint? Obviously nothing is done to remove the cause of the trouble, an additional source of irritation is created, and the practice, as we know, has already been responsible for much mischief. Œdema, inflammation, and even sloughing of the parts have resulted therefrom. Indeed, some of the most ardent advocates of these appliances recommend that they should "never be used with young children," and "only very intelligent boys are fit for this mode of treatment." It is with young children we have principally to do, and we should not like to be responsible for the degree of intelligence which would be necessary in a given case for the safe employment of these restraints. In short, I believe this treatment to be worse than useless, and the successes which have been claimed for it are no doubt to be attributed to the other measures or remedies that were simultaneously resorted to.

In view of the fact that children are most apt to "wet" when they lie on the back, and remain dry when they rest upon the side, it is suggested to tie a cloth, with a knot on the back, so that decubitus in this position is uncomfortable. With the same intent, it has been recommended to paint the lower portion of the spine with tincture of iodine—a suggestion, I think, that will not commend itself to most practitioners. But the patient should sleep on a hair-mattress with light covering, and the position in bed should be such that the urine will gravitate from the more sensitive neck toward the fundus of the bladder. Cold douches, sitz-baths, sea-bathing, and sponging the lower part of the spine at night, have been thought at various times to be beneficial, but of local treatment the most logical and undoubtedly potent is electricity. Both the galvanic and faradic currents have proved successful. Through an electrode (insulated nearly to the point), introduced into the urethra as far as the neck of the bladder, the positive current is sent, while the negative (a large, moist plate) is applied over the hypogastrium, or, which in young children is more practicable, both currents are applied externally, one over the sacrum, the other over the hypogastrium or perineum; or if this prove ineffectual, one of the electrodes may be introduced into the rectum, or vagina, as the case may be, while the other is applied over the bladder. The current at first should be weak and gradually increased each day, to the point of toleration, and the séances may last from five to fifteen minutes.

In the incontinence of urine of females, due to enlarged urethra, cauterization of the anterior half or three-quarters of an inch of the canal with argenti nitratis or sol. chromic acid has the indorsement of authority, and it seems to have proved of service in this hospital.[1] The constitutional treatment has for its object the correction of any condition of system that may give rise to irritating urine. Hence special attention is to be directed to the diet, not only in regard to fluids, which should be avoided or reduced to a minimum the latter part of the day, but also in regard to the food in general, which should be simple, highly digestible, and unstimulating to kidneys and bladder. Assimilation, primary and secondary, is to be favored and assisted in every way possible. The condition of the bowels should always be looked after, and the rectum kept free. In atonic conditions of system, scrofula, etc., iron, cod-liver oil, hypophosphites, strychnia, and cinchona suggest themselves as appropriate and important in improving nutrition and laying the foundation, perhaps, for more direct treatment.

The special remedies which have been recommended for this complaint are numerous—belladonna, chloral, ergot, nux vomica, and strychnine, bromides, creasote, camphor, digitalis, cantharides, etc. Our knowledge of the methodus medendi of these drugs is very unsatisfactory, and the widest discrepancy of opinion prevails relative thereto. As to the manner in which belladonna exerts its influence, we are remarkably at variance. Trousseau, H. C. Wood, Drysdale, Bradbury, and others believe that it diminishes the sensibility or undue irritability of the detrusor, which undue sensibility or irritability these gentlemen regard as the usual cause of the night-wettings. While Brown-Séquard, Ringer, Burney, and others take directly the opposite view, namely, that belladonna gives tone to the enfeebled sphincter, which, according to them, is always the factor in idiopathic incontinence. Whatever may be the correct explanation, clinical experience has established the efficacy of this drug in the idiopathic incontinence of children. In most cases it ameliorates the condition, and often effects a positive cure. It may be administered either in the form of extract or tincture. Older children may take the extract in pill form, beginning with an eighth of a grain at night for some days, and if improvement is manifest, the same dose continued; if not, it is gradually increased until the desired therapeutic effect is obtained, or the patient exhibits the physiological effects of the drug, such as dryness of throat and decided dilatation of pupils, but even then it should not be at once discontinued, but persevered in in smaller doses, for sometimes benefit is not obtained until the physiological effect of the drug has been manifest for a time. To younger children it is perhaps better to give the tincture in from five to thirty drops, two or three times a day, or only one large dose, possibly a drachm, according to age, at night. Of course so potent a drug as belladonna is always to be used with discretion and watchfulness, but it is well known that children bear it well, and are less susceptible to it than adults. It is often necessary to give them large doses and keep them at it before the malady yields, and when it has done so, in order to prevent relapse it is judicious to continue the remedy in diminishing quantity for some weeks or months after the complaint has entirely ceased.

[1] Dr. Kinney, THE (N. Y.) MEDICAL RECORD, May 15, 1871.

In hyperæsthetic conditions of the nervous system, in which an undue excitability of the vesico-spinal centre is suspected, chloral and the bromides seem most effectual. Chloral hydrate has proved of marked value in a number of reported cases. It is given at bedtime, in doses depending upon the age of the child, from three to fifteen grains, but it is notably a treacherous drug and requires watching. According to Bartholow, incompetency of the sphincter is met with half-grain doses of the aqueous extract of ergot with a quarter of a grain extract of nux vomica. Others also claim to have had good results with the fluid extract of secale cornutum and tincture of nux vomica. Holmes Coote recommends creasote in one-minim doses, three times daily, made in pill form, alone or combined with assafœtida and rhubarb, of each two grains. He reports five cases successfully cured by this treatment.

The fact that so many remedies have proved successful is in itself evidence that the factor in the causation of the complaint varies much, and if A succeeds with a drug which proves fruitless in the hands of B, which is so often the case, the inference is that the remedy was not equally indicated in the two instances. Thus, and finally, we must confess that for this class of cases much of our treatment is empirical, and although long experience has taught us to successfully apply "special means to special ends" the "reason for the faith that is in us" is often most obscure. When we shall possess a more intelligent appreciation of the relation of cause and effect, we shall approach these cases with more satisfaction than we do at present.

RETINAL HEMORRHAGE IN MALARIAL FEVERS.

By EDWARD W. JONES, M.D.,

NEW ORLEANS, LA.

My attention having been called to the frequent loss of sight in patients suffering from malarial fever, I have given the matter special attention, and have kept a complete record of all cases which have come under my observation and treatment or two years past. I had noticed that when there was a loss of sight sufficient to call the patient's attention, I have invariably found hemorrhagic extravasations in the retina. I have searched all literature that was in my possession and found only one author who refers to it, and that is W. R. Gomers, M.D.

The patients as a rule are not subject to these hemorrhages until they have been sick for a week or more, and then the loss of vision comes on suddenly. There is usually nothing abnormal on inspection, but the moment that the ophthalmoscope is used, the diagnosis is easy. I will give the history and treatment of five cases, taken from my note-book which will serve to illustrate this condition :

J. M——, a merchant, married ; aged thirty-four years, went out hunting in November, in the swamps, was absent two nights and days. One day after returning home he had quite a severe attack of malarial fever, of remittent type ; was given quinine by the family physician and in five days was apparently well ; on the sixth day patient suddenly lost his sight in the right eye, and becoming very much alarmed, sent immediately for his physician, who called me in consultation. The eye, to all appearances, was perfectly normal. On examination with the ophthalmoscope, I found three large striated hemorrhages above the nerve along the course of the large blood-vessels, and a round one covering the yellow spot. There was no central vision in this eye, but at both sides of the eye it was $\frac{6}{60}$. The left eye was normal. Patient was put on iron and ergot in conjunction with the quinia. The hemorrhages have faded gradually away and only a few shining spots remain. The vision is now $\frac{20}{XXX}$.

In the three following cases the patients were laboring men who had been working on a railroad in Arkansas, they were all young men and had been sick for three weeks. Two of them had many small hemorrhages in both retinæ, and the third one had one large extravasation between the nerve and the yellow spot in the left eye, but none in the right ; this patient had quotidian ague. There was considerable optic neuritis. The first two patients recovered rapidly and the hemorrhages all disappeared, whereas, in the third case, recovery was very slow. His vision in the beginning was fingers at three feet, and now, at the end of four months, is $\frac{20}{60}$: his general health is very good, and has been so ever since, after his first attack of fever.

The last case was that of a German woman, aged thirty-seven years, who had been suffering with malarial fever for a week, but had taken no medicine until her physician was sent for at this time. Her case, he said, was a mild one, but she said she had lost her sight in the right eye. On examination with the ophthalmoscope. I found many hemorrhages along the course of the larger blood-vessels, the disk presented a pale appearance, and the blood-vessels seemed to be almost empty, there was also an extensive hemorrhage in the vitreous. Vision was, fingers at two feet ; on the third day the whole of the retina became hazy, but the vitreous remained about the the same. Patient was put on the same treatment as already mentioned. This occurred some fourteen months ago ; there now remain some small dark spots where the hemorrhages were, the optic disk is white, blood-vessels diminished in size, and there is well-advanced atrophy. Vision, when first seen, was fingers at two feet, now it is $\frac{10}{60}$. Patient left the city for some six or eight months and went North. Her general health is now perfect. The sight in left eye is $\frac{20}{XX}$. Out of some twelve cases this is the only one resulting in atrophy, and I suspect that the patient had attacks of malarial fever before this last one.

The remaining cases that came under my treatment showed nothing remarkable, excepting that some recovered much more rapidly than others. If put on quinine alone, without the ergot and iron, recovery was much retarded. There being nothing abnormal on inspection in these cases, I am led to believe, and am of the opinion that hemorrhagic retinitis is much more common than the general practitioner is aware of, and if the ophthalmoscope were used in those cases where there is loss of vision in malarial fevers, hemorrhages in the retina would be found in the large majority of cases.

OLEATE OF MANGANESE.

By FRANKLIN H. MARTIN, M.D.,

FELLOW OF THE CHICAGO GYNECOLOGICAL SOCIETY, CHICAGO, ILL.

SINCE manganese[1] first received notice in this country as a menstrual stimulant, and as a remedy in functional amenorrhœa, menorrhagia, and metrorrhagia, it has been a formidable problem to the minds of therapeutists, and pharmacists to get it into an acceptable shape for administration. The permanganate of potash, the original preparation used for experiments and administration in any form, is liable to act as an irritant to the stomach, and is very objectionable to many on that account. It has in many ingenious ways been made into pills, but as these pills must of necessity have for their basis kaolin, or some other inorganic substance, the drug is not satisfactorily observed. The compressed tablets of Wyeth & Brothers and others, are objectionable in many cases of irritable stomach, because of the irritating undiluted drug coming in direct contact with its mucous membrane The binoxide of manganese has, on account of its insolubility proved to be almost inert. On account of the many difficulties of administration, therefore, this valuable drug has not met with the warm reception that is its

[1] See Author's article in THE MEDICAL RECORD, September 29, 1883.

due. Through a suggestion of Dr. S. S. McArthur, I have succeeded in having an oleate of manganese prepared.

Method of application.—Of a twenty per cent. solution of the oleate, I should recommend that one drachm be applied to the abdomen of the patient, and its absorption promoted by friction produced by vigorous rubbing of the surface with the palm of the hand or with the fingers. The rubbing should be continued until the oil has entirely disappeared by absorption.

In cases where it is found impracticable to apply it to the abdomen on account of tenderness, it may be applied to the spine or the inner surfaces of the thighs.

In cases of amenorrhœa it should be applied if possible every night for a week preceding the expected menstrual period, or at the time the menstruation is due, and until it makes its appearance. In cases of menorrhagia or metrorrhagia it can be applied in smaller quantities every night until the desired effect is produced.

I am very anxious to see the profession give this preparation a good trial, because if there is any great value in this drug, it can only become popular as a remedy in some such unobjectionable form.

The oleate was prepared as follows: A solution of sulphate of manganese was made in distilled water, and to it a solution of sodium oleate was added. On mixing these two solutions gradually and with constant stirring, a precipitate of oleate of manganese resulted. This precipitate upon heating changed to a putty-like mass. This was thoroughly washed several times with warm distilled water, to remove the sodium sulphate, and the resulting putty-like mass was the pure oleate of manganese. This oleate, when dissolved in oleic acid to the required per cent., is ready for use.

2139 Wabash Avenue.

Progress of Medical Science.

Treatment of Cardiac Hypertrophy Occurring in Youth.—Germain Sée observes (*Archives of Pediatrics*, May 10, 1885) that in the hypertrophy of adolescence, as well as in the hypertrophic ectasis of childhood, the treatment should be exclusively cardiac, in other words, general tonics should yield to those which have a direct action upon the heart. Meats, however, raw or rare, and finely divided, should be partaken of in abundance. Digitalis is exclusively used (by the author) for temporary purposes; convallamarine is always to be approved, and the same is true of iodide of potash, the latter being considered one of the most powerful cardiac and respiratory agents. Digitalis is recommended for children in the form of a cold maceration of the powdered leaves, the dose being five to ten centigrammes of the powder. It is indicated in the arythmical forms of hypertrophy, and especially in cases of infantile cardiac dilatation, but its continued use provokes intolerance, loss of appetite, vomiting, and in some cases a kind of paralysis of the vagi. Iodide of potassium acts not only upon cardiac dyspnœa and the so-called cardiac asthma, but it has a powerful influence upon the myocardium as well as upon the vessels, increasing their contractile energy. It facilitates respiration at once, and effects a lasting tonic action upon the heart. From eight to fifteen grains may be given daily in the class of cases under discussion. Usually its use may be continued for months with no greater discomfort than the iodic coryza, or anorexia. Convallamarine is usually well tolerated, rarely troubles the digestive functions, and has no cumulative action like digitalis. In a very extensive experience with this drug, the author affirms that it has always sustained the contractile force of the heart, regulated the cardiac rhythm, produced a cessation of palpitations, and facilitated respiration and diuresis. It is very soluble in dilute alcohol, and may be given to children in doses of one-third to two-thirds of a grain. It has also been successfully given in valvular troubles, in Basedow's disease, in angina pectoris, palpitations, and all the painful affections of the heart. The unfavorable symptoms quickly disappear under its use, especially when combined with the iodide, and the commendation which it receives is unqualified.

Sanitation by Fire.—Colonel J. M. Keating (*The Sanitarian*) read a paper before the American Public Health Association, entitled "The Ultimate of Sanitation by Fire." From the testimony adduced in his paper, he concludes that the cremation of excreta and all household wastes and street wastes would: 1, Preclude the possibility of the return of such wastes in any deleterious form, as is the case now universally; 2, it would save to all cities two-thirds their present water-supply, and thus increase the quantity for personal sanitation; 3, it would put a stop beyond all question to soil saturation and sewer-gas; 4, it would reduce scavenging to the minimum of expense, and save much of the cost of hauling and of great sewerage works, like those of Boston and London; 5, it would put a stop to all the nuisances complained of from defective plumbing; 6, it would prevent the silting up of harbors with excretal matter, and their being choked with silt; 7, it would prevent the pollution of rivers, and so prevent the wholesale destruction, as is now the case, of fish, the poor man's food-crop; 8, equally applicable to hamlets, villages, towns, and cities, it would put a stop to the privy and cesspool system, and thus prevent the saturation of soils, which frequently drain into the water-courses that are the sources of supply for great cities; 9, it would solve all the problems that now vex sanitarians, from house connections to the outflow through which sewage finds its way into rivers and harbors: 10, it makes a finality of all the wastes of cities, of every kind, character, and description, the result being, according to Shaw's method, an ash of great value to farmers, and clinkers that have a special commercial value for builders.

Cancer of the Testicle in Infants.—Dr. Monod, of Paris, after describing a case of cancer of the testicle in a child aged four, gives an analysis of twenty-seven cases of cancer and sarcoma of the testicle in children. In more than half of the cases it is in the first year that the disease originates; after the fourth year cancer is exceptional. The influence of heredity upon the production of the disease appears to be null, that of traumatism is open to discussion, and may, at any rate, act as a determining cause. The clinical details of the cases are always the same. An apparently healthy child has an indolent, progressively-enlarging tumor of the scrotum. The tumor is usually noticed in the earlier months of life, sometimes even at birth; it occupies the testicle, is unilateral, smooth, ovoid, resisting with a sense of fluctuation, and heavy. The spermatic cord is always healthy, and usually the lumbar and inguinal glands. Hæmatocele may be thought of, but a puncture reveals the nature of this case. The growth of the tumor is rapid. The results of castration are not encouraging; the operation, when the case could be followed, having always been succeeded by a generalization of the new growth, most often in the lymphatics, and sometimes in the lungs as well, death taking place within the year. Histological examinations, though too rare for safe inference, seem to show that the disease is more often sarcoma than cancer.—*Annals of Surgery*, May, 1885.

Spontaneous Rupture of the Œsophagus.—At a recent meeting of the Midland Medical Society, Dr. Purslow showed a specimen of spontaneous rupture of the œsophagus into the left pleural cavity, from an infant aged eleven months. There was no appearance of ulceration in the wall of the stomach or œsophagus, and no trace of a foreign body. The child was admitted with bronchitis twelve hours before death, and the fatal termination was sudden and unexpected, and preceded by convulsions.—*Birmingham Medical Review*, May, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 27, 1885.

MEDICAL SOCIETY WORK, PAST AND FUTURE.

THE month of June sees the work by medical societies —national, State, and local—wellnigh completed. *Pari passu*, as the thermometer mounts, evidently the medical intellectual activity declines. By July 1st New York's medical societies, public and private, are ready for a state of æstivation which will last through July and August, and for the most part through September.

Of the three professions—medical, theological, and legal—the former, during the warm season, takes the most complete intellectual repose in so far as making a public expression of ideas is concerned. The clergymen come next, who, if they do not refrain from speaking once a week, placidly preach old sermons to congregations belonging to exchanging brethren. The lawyer's rhetoric may cool off a little with summer's heat, but its temperature has to be more even the year round.

What has been done in New York medical societies during the winter? A year's work has practically come to an end, and now a good opportunity is afforded for retrospection. All will agree that a number of valuable papers have been read and discussed in the various medical assemblages, papers which have had upon the profession a great influence, after having been read, through a wide dissemination by publication; nevertheless no one will dissent, we think, when we say that much more might be done, and that the medical societies another winter might take a higher and more advanced position, and wield a more powerful influence in the community and exact more deference from abroad.

How can this desirable state of affairs be attained? How can New York's medical societies so improve that their influence shall be increased at home and abroad?

This improvement depends on two factors—the presidents of the societies and the members. To be the presiding officer of a medical society requires especial genius. He is to the members what the bar of magnetized iron is to the induction coil. The more complete the mutual relationship, the more striking and powerful the result.

The other important factor—the members—are responsible for much. They must be interested, and to be this they should attend regularly. It is a great pity that often the older and more experienced physicians are not present at our societies; they appear meteor-like, at rare intervals, to read papers, but they do not take the time to come and discuss others. Absorbed in their profession, success in which has already been attained, they leave discussion and theorizing to younger men who are striving to climb the ladder. Possibly this is more encouraging to medical aspirants, but it is not as instructive to all, and lowers the standard of net results. The medical is the most exacting of all the professions, and leaves little time for scientific investigation and record of observation, which often leads to a scarcity of suitable papers to read before societies, or to the presentation of these too hastily and superficially prepared.

The medical man, if he has not much chance to write, likes to talk. Untrained to oratory and logic, as is the clergyman and the lawyer, he is not always fluent in the expression of his ideas, which, however valuable they may be, lose much through incoherency of utterance and rambling from the point in hand. So conspicuously is this fault displayed at times, that ill-natured brethren in the profession jeeringly remark: "Such and such a one only speaks because he wishes to see his name among those who talk at societies, and thinks thus to advertise himself."

Such an imputation is manifestly unjust; but doctors will lay themselves open to such a slander so long as they speak wide of the mark, and in a tedious manner.

To the members belongs the duty of suppressing "society bores." It will be a difficult task; but if it is accomplished, the result will tell in great advancement of the standard of society work, increased interest, and increased attendance.

We are inclined to believe that there are too many medical societies in New York, public and private, to flourish well and to produce the best results for the profession. It is true, the more societies the greater opportunity for distinction in the way of official appointment, so that Artemus Ward's ideal of an army, all officers, can be more nearly approached. The rambling talkers and society bores are distributed more evenly; but the forces which best result in society work are also scattered. We cannot help thinking that better work would be accomplished if the societies were to concentrate themselves. Let the County Medical Society, the Academy, and the Pathological Society represent the profession in general. The sections in the Academy would provide society work for specialists in every department, except the pathological, which should be continued in the Pathological Society.

To attain the happiest results in society work "the lion should lie down with the lamb;" or, to abandon figurative speech, the "Old Code" and "New Code" differences should be forgotten in the one aim of the scientific advancement of the medical profession.

In closing, we would say that, possibly, if the societies met in well-ventilated halls, the net results of intellectual endeavor would be greater. It may be interesting to such experimenters as Pettenkofer and Voit to know how much brain-work can be accomplished in an atmosphere of carbonic dioxide, and to have it proved, as it certainly has been this past winter, that doctors can carry off the palm in this respect; but having once been demonstrated, would it not be well to try a contrary experiment, and see another winter what the quality of society work would be in rooms or halls with say a moderate supply of fresh air.

THE LIMITATIONS OF ABDOMINAL SURGERY.

Some interesting speculations are suggested by reading the preface of Sir Spencer Wells' latest volume, which we notice in another column of the present issue. Like most other surgical expedients of any magnitude, abdominal section has had to fight its way against ignorance, prejudice, and inherent difficulties. One by one these have vanished or have been overcome. The position of the profession on this subject is to-day a proud one. We are led to inquire as to the possibilities of still further advancement. The paper of Mr. Treves, read in London some time ago, as well as the more recent one by Dr. Burchard before our own Academy, show us that "forward" is still the watchword. Long and careful discussion must, in matters of this kind, necessarily precede decisive action, and the discussions of the last few months on topics relating to abdominal surgery have been of a healthy nature, characterized by an earnest search after *truth rather than a desire for controversy.*

It is interesting to note what Sir Spencer Wells thinks of our present and possible future position. Referring to the removal of abdominal tumors, he says in his preface: "There is one fact which stands out with ominous significance in all our records, whatever may be our diagnostic accuracy and our operative skill; our success in the treatment of these cases is fatally affected by the influence of septicæmia. We have already reached as great an amount of success in the results of ovariotomy as can reasonably be hoped for, and shall in like manner approach success in the results of the extirpation of other organs," and he intimates that we cannot regard the battle as fully won until our antiseptic precautions shall much more fully than at present protect our patients against the ravages of septicæmia.

This is certainly a frank and modest statement from one whose labors have been crowned with such success. In alluding to the operative treatment of peritonitis, he notes Mr. Treves' advocacy of it in cases resulting from injury, gunshot-wounds, bursting of an abscess, and specified forms of perforation, but he adds the "caution against putting off the operation until too late—until the patient is dying of septicæmia."

In Wells' last series of one hundred ovariotomies but eleven died; of Lawson Tait's thousand cases of abdominal section (the peritoneum being involved in each) the mortality percentage was but nine and three-tenths Record, January 3, 1885). We have no reason to doubt but that in time to come a like favorable showing will attend laparotomy for acute idiopathic peritonitis. Of course, operative surgery will always be limited by conditions arising from previous ill-health, diseased kidneys, and the various constitutional vices. These must be a constant factor of failure. All true surgery is conservative. In abdominal section for peritonitis we remove no member and perform no mutilation. It is in the truest sense conservative.

INSTRUCTION TO TEACHERS.

We are glad to note that public interest is becoming aroused in regard to giving teachers instruction concerning the first symptoms of contagious diseases. A correspondent writes us from Bangor, Me., that such instruction has been given in the schools of that city for the past year, and that already great aid has been rendered in preventing the spread of disease among the scholars. The nature of the instruction given is such that the teachers are made watchful and careful in regard to their pupils, and often a so-called "spunky" fit is seen to be really the precursor of an actual sickness. It is one of the most cheering signs of the times in educational matters that the bodies of our scholars, as well as their minds, are being looked after. The practical inauguration of such a plan of instruction is not a difficult matter. Here in New York, if anywhere in the whole world, it is imperatively needed. The subject should be taken up by our city Board of Education. Let them organize the teachers of each grammar-school into a class to meet in their own building. Plenty of able men in the profession will volunteer their services as lecturers. Let the zeal of the teachers be stimulated by their receiving—after an examination on the subject-matter of the lectures—from the Board a certificate of proficiency in knowledge concerning the initial symptoms of the common contagious diseases which almost daily show themselves in every school-room in America. In short, let the method of instruction and examination imitate that of the Society for Instruction in First Aid to the Injured. Preventive medicine is the coming glory of the profession. Such a plan as we propose will entail very little work upon the officials of the Board. It can be accomplished with a trifling sacrifice of time on the part of the teachers, and, if held in the daytime, the lectures are absolutely free from expense to the city. Scores of our ablest practitioners will take hold of the work with heart and soul, if only given an opportunity. We must not allow Bangor to surpass New York in zeal for public hygiene.

BRAIN NOMENCLATURE.

Professor Wilder, the president of the American Neurological Association has distinguished himself in this direction. He has founded a new science which he calls *neuronomy*. His industry in coining words is even greater than that for searching out new cells, nerve-tracts, and blood-vessels of the brain, which is considerable. No one will dispute his title to the fame of having devoted more time to the naming of the contents of the cranium than any other English-speaking man. One is inclined to exclaim, Heaven forbid another from a like undertaking! The study of the brain now has become so complicated that it requires a bold determination on the part of the student to undertake it. It is as if he had entered a primeval forest in which wanderers, according to their own sweet will, had blazed trees in every direction until all the monarchs of the forest had received one or more instructing gashes, resulting in a wilderness more confusing than ever—the old trails becoming lost, and intermingling with the new. Could all the explorers in brain anatomy come together, settle upon a common basis, and adopt a universal nomenclature which should pass current everywhere, a great boon would be conferred.

Possibly Professor Wilder could succeed in pressing his nomenclature to a universal adoption, but it will take more than one generation to receive it with a cheerful acquiescence, and to accord to it the credit which we to-day are slow to give, and the appreciation which, justly or not, is withheld.

CHOLERA PATIENTS AND THEIR PHYSICIANS.

The scientific devotion of physicians in ferreting out the causes of cholera is little appreciated by the world at large. The intricacy of the problem, the difficulty of its solution pique the investigating zeal of the medical men in those countries in which the disease is raging, and their brethren in other countries watch with eagerness every detail of their work. On this side of the water we are surprised to hear of the opposition the doctors encounter among the poor and afflicted people.

Last summer in Marseilles physicians were in danger of being mobbed as they went about the streets, and now in Spain the telegraph brings us the same report. The people are afraid of the physicians and refuse to let them come near them.

It has been said that in no country are doctors so universally employed, or so much respected as in America. It therefore occasions the more astonishment here to learn of the lack of confidence displayed by the populace in the time of their extremity in the doctors. That such scenes could be enacted in New York, should cholera appear among us, seems hardly credible. The lowest classes here are more educated and enlightened, and, to judge from dispensary practice, are so liberally endowed with faith in the medical profession that to repulse it and drive it from them in the time of their extremity would be the farthest from their thoughts.

THE UTERINE CIRCULATION AND THE MECHANICAL PATHOLOGY.

Most American gynecologists have, a long time since, emancipated themselves from the mechanical pathology of uterine disturbances. The late Marion Sims was, perhaps, the last prominent man to lay great stress upon it. English gynecology, which has certainly been behind that of American in many respects, has also been slow to give up the old teachings with regard to the serious mechanical results of topographical uterine aberration. At a recent meeting of the Obstetrical Society of London, Dr. John Williams presented the results of his studies of the uterine circulation, and dealt another effective blow against the mechanical pathologists. The arrangement of the vessels of the uterus, as observed by Dr. Williams, is as follows:

"The ovarian and uterine arteries run along the sides of the uterus and give off numerous branches, which proceed horizontally inward and form circles around the organ; from these vessels run toward the uterine cavity in a direction perpendicular to the surface. It results from this that each portion of the uterus has its blood-supply secured to it at its own level, and is not dependent upon any segment above or below it. The arrangement of the veins is similar, and secures a free return of blood; the venous anastomoses of the veins outside the uterus are numerous and free, and," as *The Lancet* observes, "it is an almost every-day observation that the ovarian vessels may be tied without embarrassing the return of blood from the uterus in any serious or permanent manner. The chief practical importance of the paper lay in the assertion of the author that a ligature may be tied completely round the uterus, at any point above the vaginal injection, without affecting the supply of blood either above or below, and that, therefore, flexions of the uterus can have no effect upon the blood-supply, in the way of causing congestion."

Naturally, this statement awoke some discussion. Dr. Grailly Hewitt, the most prominent advocate of the mechanical theory, admitted that the vascular arrangements of the uterus were competent to prevent congestion in slight and temporary cases of flexion, but he asserted that if this were severe and persistent congestion would probably follow. Very little of a positive character, however, was brought forward against Dr. Williams' statement, and the sentiment of most of the speakers appeared to be with him. The etiological divorce between flexions and congestions seems now to be established on physiological and anatomical, as well as pathological grounds. Not that flexions are never followed or accompanied by congestions, but that the relations between the two conditions cannot be satisfactorily explained on mechanical grounds.

VISCERAL POPULARITY.

For those of the laity who do not regard the body as a homogeneous solid, there is differentiated a single organ, or portion of an organ, which represents to the seeker of lost health the seat of his or her woe. This all-important organ in ancient times was the heart, as the genius of our language shows. To the Greeks it represented brain, nerve, blood, everything which goes to make up the being of the individual, so that if he were very well, he was "hearty." There are more words compounded with heart to represent conditions mental, moral, and physical, than any other in the language. This all happened because the heart was the popular organ of the body at the time our language was becoming crystallized. If the popular organ of that day had been, as it is of this, the liver, we would not have had the meagre array of words we now have compounded with liver. Those which are, mean something else, as livery-stable, or the the word "livery," which has to do with the outside of the man and not at all with the predominating organ within. Possibly it was well for the language that it was formed at that period, when everything, whether good or bad, proceeded from the *heart* of man, as there was then unanimity of thought and feeling, which does not at all exist in this year of grace, 1885.

The organ of the body which is the fetich varies now for class and for individual. Perhaps, among the most ignorant, the kidneys are oftener held accountable for any aberrations from a state of health, and the kidney, whose wanderings are recognized by science, becomes even more errant than medical men are wont to allow, and locates itself according to the ideas of its owners any and everywhere.

Among the more educated classes the nervous system comes in for its share of attention. For practical purposes, it is divided into brain and nerves; and of the brain, the *base* is the favorite seat of trouble. The feminine portion of the community claim "the nerves," though they are not allowed the monopoly.

The stomach is too matter-of-fact an organ to hold the fancy and allegiance of any but dyspeptics. It was

somewhat popular in the olden time, as is shown by the fact that certain philosophers, more learned in metaphysics than anatomy, located the soul therein.

The spleen has never claimed much attention from its owner. The ancients made it the seat of anger and melancholy. At the present day it is, for the most part, ignored. It must certainly be a rare thing for a physician to be called upon to prescribe anything "to act upon the spleen."

As for the pancreas, it is almost never alluded to. Once, in fact, a young woman told a New York neurologist that she thought her pancreas did not emulsify sufficiently the fat which she had eaten with her food. The worthy man was so horror-stricken at this display of knowledge and its application, that he at once exercised all his mighty influence to banish forevermore from the sight of woman a book on anatomy and physiology. This dangerous apple of knowledge, that she possesses a pancreas, should be guarded with flaming sword from any daughter of Eve who should desire to possess it.

This brings us to the important question of the subject, which otherwise might not be worthy of discussion, except as a curious ethnological fact. Is it well for the laity to have a pet organ; to know, for instance, that they "have a liver," which renders them an easy prey to the patent-medicine vendor of pads and pills?

Should physicians advocate education in this direction? Should they try to mould and shape popular opinion? If this question is answered in the affirmative, a second immediately arises, How should this be done? Then, again, were this done in the best manner possible, unless all became physicians, which obviously would be exceedingly undesirable, would there not still remain a troublous pet organ, all the more troublesome because the owner would be able to put his hand over the region of it and centre all his feelings and imaginations upon it?

It certainly will not do to try to educate the present generation out of the idea of its pet organ. In all reforms one must turn to the rising generation. It becomes, therefore, all the more important to decide at once upon the matter, that no time be lost.

The relation of the physician to the existing popular organ is one of extreme delicacy. To roughly, rudely, or contemptuously handle it will often cost the physician his patient, who insists—and why not rightly?—that it shall be treated with the greatest consideration.

THE CONDITION OF GENERAL GRANT.

The progress of the disease from which General Grant is suffering is, barring accidental complications, necessarily slow. Comparing the condition of the patient with what it was a month ago, the changes which have taken place can be appreciated. Taking this period of time into consideration it can be said that the swelling under the angle of the lower jaw on the right side has increased, has become harder and more deeply fixed. It has shown a tendency to progress in a direction downward and forward upon the right side of the neck; the infiltration extending into neighboring glandular structures. The lancinating pains in those parts, although fortunately not frequent nor severe, have a significance which cannot be ignored. The ulceration on the right side of the base of the tongue has become deeper and more irregular, although its superficial area has not perceptibly increased. This is the seat of pain occasionally in swallowing and when certain examinations of the throat are made. The destructive process on the right side of the uvula is apparently quiescent, although a new portion of the margin of the palatal curtain is showing a tendency to break down.

The voice has been reduced to a whisper, due partly to inflammatory involvement of the vocal cords, and partly to nervous atony of the latter. There is some impairment of general strength and some loss in weight, although the appetite is unchanged and the usual amount of nourishment is taken. The removal to Mount McGregor has so far proved beneficial. It has enabled the patient to recover lost ground, and thus in a measure has counterbalanced the effects of his local malady.

News of the Week.

A Doctor Indicted for Manslaughter.—A physician of Batavia, N. Y., named Dr. H. J. Paton, presumably an irregular, his name not being in the Green Book, has been indicted for manslaughter in the second degree, the charges against him being that he killed a boy eleven years of age, whom he was attending in April, by administering hypodermically an overdose of morphine. The doctor has lived in Batavia only two years, but has secured, it is said, a considerable practice.

The Cholera in Spain continues its slow progress. In one day (June 22d) there were 771 new cases and 349 deaths, occurring in ten different cities or provinces.

The Vermont Medical Society held its semi-annual meeting at Bellows Falls on June 25th and 26th, under the presidency of Dr. Joseph Draper, of Brattleboro.

The Ohio State Medical Society at its last Annual Session elected the following officers: President—W. Morrow Beach, of London; Vice-Presidents—Drs. H. C. Gill, H. R. Kelly, Thomas Mackebright, and J. D. Robinson; Treasurer and Librarian—Dr. T. W. Jones, of Columbus; Secretary—G. A. Collamore, of Toledo; Assistant Secretary—Dr. E. C. Brush, of Zanesville. Akron was chosen as the place of the next annual meeting, the time being the first Wednesday, Thursday, and Friday of June, 1886.

An International Faith-healing Conference was held in London recently.

The Columbus Medical Journal discourses as follows *à propos* of the International Congress and its Committee: "We received the list of appointees some time ago, and failed to find anything to criticise. We thought the names had been selected with great care, to secure men of, as far as possible, national, if not international, reputation. But not so with all. The Committee had made no provision for the eloquent champion of the mothers of Texas; they had ignored the oleates; they had not tested all their appointees by the *shibboleth* of the Code; they had not given the 'rural deestricts' their *numerical* ratio of the offices; whole States and Territories were entirely ignored; even Ohio had but

fourteen, and of these her metropolis had all but one, while New York, Philadelphia, and Boston were liberally remembered. And so there was a kick. The original kick was kicked, it would appear, in Texas, whence—in the vigorous, but slightly *mixed*, figure of the *Courier-Record*—it (the kick) 'rolled into one mighty billow and at New Orleans inundated, swamped, aye, *snowed* under the whole arrangement.' And so it was decided to increase the size of the Committee, and otherwise so arrange matters that the ranches of Texas, the prairies of Kansas, the mines of Colorado, and the forests and wheat fields of the great Northwest should all be 'represented' among the officers of this Congress. Verily, we trust the original committee, and their rustic accessories, may duly exercise, the former, patience, the latter, humility, and both moderation, to the end that the Congress may be a success; for unless they do this we greatly apprehend the Texas kick will overturn the fat into the fire."

A New Medico-Legal Society has been organized in Rhode Island by the medical examiners of the State. —*Medical News.*

The Maine Medical Association held its annual meeting at Portland, June 9th, 10th, and 11th, Dr. T. A. Foster presiding. A committee was appointed on the Medical Registration Bill. It was reported that a satisfactory Board of Health had been organized. Dr. Sumner Laughton, of Bangor, was elected President; Dr. Charles D. Smith, of Portland, Permanent Secretary. The next meeting will be held in Portland, June 1st.

A Pharmacy Law compelling the registration of druggists has been enacted in Massachusetts.

Another Noble Doctor.—Prof. Richard Volkmann, of Halle, has been raised to the order of nobility.

The University of Marburg, and in particular the medical school, has received a legacy of 800,000 marks from the estate of the late Countess Louise Bose.

The Alumni Association Prize of the College of Physicians and Surgeons, New York.—This prize, of five hundred dollars, offered to the competition of Alumni of the College, will be awarded at the next Annual Commencement, May 11, 1886. The competing essays must embody the result of *original research* upon some medical subject. They must bear a motto or device, and be accompanied by a sealed envelope bearing the same motto, and containing the author's name and address. Essays should be sent before April 1, 1886, to any of the undersigned in New York City:

E. C. Seguin, M.D.,
J. West Roosevelt, M.D.,
M. Allen Starr, M.D.,
Committee.

Intermediate Transplantation of a Pivot Tooth with Restoration of Function.—A lady in South Bend, Ind., who had a false tooth set on a pivot, sneezed it out the other day while feeding chickens. An old hen thought it was a grain of corn and swallowed it as soon as it struck the ground. After a long chase the hen was captured, beheaded, its crop opened, the tooth found, and restored to the lady's mouth, where it afterward helped to masticate the old hen.

The Wisconsin Medical Code of Ethics.—The discussion that has raged in the New York Medical Society, and that has caused the expulsion of some of the ablest physicians in the world from the American Medical Association, has reached the Wisconsin Medical Society, and given rise to the usual and inevitable strong feeling. It has been brought up by Dr. Bartlett's address, in which he attacks the Code of Ethics which prohibits members of the Society from recognizing practitioners of another school.—*Milwaukee Sentinel.*

Death of Dr. Nachtigal.—This well-known traveller died at Cape Vincent, Africa, on May 5th. He was born in 1834, and for a time practised medicine in Cologne. Having acquired phthisis, he went to Algeria, and was later second physician to the Bey of Tunis. Since that time he has obtained a wide reputation as an African explorer, and, at the time of his death, had the charge of an important mission in connection with the German colonial enterprises in Africa.

The French Association for the Advancement of Science will meet this year at Grenoble, on August 13th, under the presidency of M. Verneuil.

Navy News.—Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending June 20, 1885: Passed Assistant Surgeon George Arthur, granted leave of absence for one year, with permission to leave the United States; Passed Assistant Surgeon C. W. Deane, granted leave of absence for three months; Medical Inspector C. J. Cleborne, as member of Medical and Naval Examining Boards, Philadelphia, Pa., June 22, 1885; Passed Assistant Surgeon George C. Lippincott, detached from temporary duty, Naval Academy, and waiting orders; Surgeon Benjamin S. Mackie, as member of Medical and Naval Examining Boards, Philadelphia, Pa., June 22, 1885; Joseph Shafer, commissioned an Assistant Surgeon, Active List, June 12, 1885.

New Health Journal.—*The People's Health Journal* is the title of a new monthly periodical, published in Chicago and edited by Drs. L. D. and S. Ida Rogers.

Actinomycosis not a New Disease.—Mr. Shattock, at a recent meeting of the London Pathological Society, showed two specimens of actinomycosis of the liver, which he had discovered in the museum of St. Thomas' Hospital. The specimens were over twenty years old, but the presence of the fungus was distinctly shown under the microscope. Thus the disease itself is not new, although our knowledge of it, at least in man, is comparatively recent.

The Association of Ex-Internes of St. Luke's Hospital.—This Association was organized some three years ago, with the object of promoting and maintaining a feeling of good-fellowship among the former internes of St. Luke's Hospital. It has at present upon the roll the names of about forty members, residents of New York and the vicinity. The second annual dinner of the Association was given on the evening of Tuesday, June 9th, at the University Club, Twenty-sixth Street and Madison Avenue.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held in New York, June 17, 18, and 19, 1885.

First Day—Wednesday, June 17th—Afternoon Session.

The Association met in the Hall of the New York Academy of Medicine, and was called to order at 3 P.M. by the President, Dr. Isaac Ott, of Easton, Pa., who delivered a brief address before retiring from the Chair.

Dr. Ott directed attention especially to

THE RELATIONS OF THE NERVOUS SYSTEM TO THE TEMPERATURE OF THE BODY,

and said that the researches of various observers had led up to the conclusion that the temperature of the body, like the heart, is under the control of the nervous system. If this be true, the question arises, where are the heat-centres located? In 1884, Dr. Ott published a paper, showing that in the vicinity of the corpora striata were centres having a relation to the temperature of the body. Recently Aronsohn and Sachs have arrived at the conclusion that in the cerebrum are similar centres, whose situation corresponds to the corpora striata. During the last few months, Dr. Ott has attempted to more definitely map out the centres, and finds them located in the anterior inner part of the optic thalami.

In his experiments he used D'Aisonval's calorimeter, surrounding it with felt and feathers, and Voit's respiration apparatus, which served to note the quantity of air by its large meter, and at the same time was used as an aspirator.

These centres are veritable heat-centres, and not due to vaso-motor deflections. Removal of different parts of the cortex causes only a temporary rise, while the rise in the centres concerned lasts two or three days, and often amounts to about 4½° F.

Dr. Ott then introduced Dr. Leonard Weber, of New York, Vice-President elect, who discharged the duties of President Dr. B. G. Wilder, who was unavoidably absent.

ELECTION OF NEW MEMBERS.

The resignation of Dr. John J. Mason was accepted, and he was elected associate member.

Drs. Philip Zenner, of Cincinnati, O., and M. Allen Starr, of New York, were elected active members.

The Secretary, Dr. G. M. Hammond, of New York, read several

LETTERS OF REGRET FROM ABSENT MEMBERS,

and others from Dr. J. S. Jewell and Dr. H. Gradle, of Chicago; Dr. H. D. Schmidt, of New Orleans; Dr. C. K. Mills, of Philadelphia; Dr. J. T. Eskridge, of Philadelphia (now in Colorado for his health); Dr. S. F. Denillo, St. Petersburg, and Dr. A. Forel, of Zurich, thanking the Association for the honor of associate membership.

ELECTION OF OFFICERS.

President—Dr. Charles K. Mills, of Philadelphia.

Vice-President—Dr. V. P. Gibney, of New York.

Secretary and Treasurer—Dr. R. W. Amidon, of New York.

Councillors—Drs. Geo. W. Jacoby and E. C. Seguin, of New York.

Dr. A. D. Rockwell, of New York, then read a paper entitled

A CASE OF CHRONIC MYELITIS—RECOVERY.

It was a case of complete recovery from chronic, supervening upon acute, myelitis, occurring in the person of Miss B——, sixteen years of age, referred to him by Dr. J. O. Farrington. There was complete abolition of electro-muscular contractility, with bed-sore and paralysis of rectal and vesical sphincters. The acute attack followed immediately upon exposure to cold, and within a week there was complete paralysis of the lower limbs, and after six weeks a bed-sore developed in the region of the last lumbar vertebra.

Dr. Rockwell gave a most unpromising diagnosis, and it was only at the earnest solicitation of the father that further active treatment was attempted, which consisted in the use of galvanism, about thirty volts, repeating the application every other day, over the legs and the lower portion of the spine. Three weeks of persistent effort failed to elicit any response. The bed-sore, however, began to improve, and at the end of the fourth week faint muscular contractions were observed, and at the end of another week they were so well marked as to indicate distinctly that they were the reactions of degeneration.

The practical value of the case, so far as related to the pathological side, was in the distinct negative rather than in any affirmative. It was self-evident that, however much structural change had taken place in the way of atrophy of nerve-cells, or induration or overgrowth of connective tissue, the nutrition of the nerve-cells had not been sufficiently impaired to be beyond the influence of the reparative process.

Dr. E. C. Seguin, of New York, regarded the case as one of a somewhat modified polio-myelitis with some extension, perhaps, to the central gray matter; but certainly it was not in the category of transverse myelitis, of which he had never seen a case of recovery. The case was especially instructive with reference to the time employed in the treatment, which allowed chance for spontaneous restoration, although the galvanism had much to do with expediting the cure, and the restoration of the muscles.

The discussion was continued by Drs. Starr, Birdsall, and Gibney, of New York, and Dr. Gray, of Brooklyn, and closed by Dr. Rockwell, who said that he had omitted to state that all the groups of muscles were affected alike, that there was absence of patellar tendon reflex in the beginning which had returned, and that there was a good deal of agitation of the ankle when the foot was flexed.

Dr. M. Allen Starr, of New York, then read his inaugural paper on

THE METHODS OF STAINING NERVOUS TISSUE,

in which he gave the technique of Weigert's hæmatoxylin method, Weigert's acid fuchsin method, Seguin's modification of the anilin blue method, Sahli's methyl blue stain, Sahli's double stain with methyl blue and acid fuchsin, Sahli's methyl blue stain, and last, the saffranin stain.

The paper was discussed by Dr. E. C. Seguin, of New York, after which the Association adjourned to meet at 8.30 P.M.

First Day—Wednesday, June 17th—Evening Session.

The Association was called to order by the Vice-President, Dr. Weber.

Dr. George W. Jacoby, of New York, read a paper

ON THE USE OF OSMIC ACID IN PERIPHERAL NEURALGIAS,

in which he first gave a *résumé* of the cases reported by Neuber, Eulenburg, A. Wölfer, and Jas. Merces.

Dr. Jacoby treated his cases by the hypodermic use of a one per cent. watery solution of osmic acid, using half a gramme at each injection, inserting the needle as near as possible to the point of severest pain, and into the connective tissue surrounding the affected nerve. The pain caused by the injection was, in many cases, exceedingly severe, and occasionally local changes were produced. The action of the drug is probably a local one, no constitutional symptoms whatever being produced. Dr. Jacoby gave the details of only three of his cases: two

of sciatica and one of cervico-brachial neuralgia. His whole number of cases was eighteen, which showed eight cures, two improved, eight unaffected. Of the eight cured cases, five were sciatica. All the cured cases were old cases; the unimproved cases were three recent and two old ones. From his cases it seemed that the sciatic nerve was most impressionable to the action of this remedy, and that old inveterate cases presented the best chance of success.

The conclusions reached were (1) that we have in osmic acid a remedy which is of service in the treatment of certain cases of peripheral neuralgia and in some cases when every other remedy has failed; (2) that osmic acid is not an antineuralgic, its action is very localized, and it frequently fails when other remedies succeed; (3) that its employment is, in most cases, very painful and not altogether free from danger; (4) that it is dangerous to implicate a motor nerve in the injections.

Dr. Sachs, of New York, on invitation, participated in the discussion, and said that his experience in the use of osmic acid in the treatment of neuralgia had been only partially satisfactory; the impression which he gained being that in most cases it was unreliable. The drug was doubtless admissible where everything else had been tried and failed.

Dr. Seguin, of New York, had not used osmic acid, but he had had some experience in the application of the same general principle, namely, deep-seated counter-irritation by hypodermic injections of different drugs. He had seen two cases of sciatica cured by such treatment with nitrate of silver. He had also seen two cases of radial neuralgia, in which osmic acid was used without any relief, but they were not suitable cases for the remedy.

Dr. Jacoby thought that if Eulenburg's experiments were reliable, the benefit was not always due to counter-irritation. The remainder of the session was devoted to demonstrating the results of staining nervous tissue by different methods, and by means of a large number of sections, prepared by Drs. Starr and Seguin, after which the Association went into executive session.

Second Day—Thursday, June 18th—Afternoon Session.

The Association was called to order by the President, Dr. Burt G. Wilder, of Ithaca, N. Y.

The first paper was read by Dr. V. P. Gibney, of New York, and consisted of a report of two cases of

SPINA-BIFIDA CURED,

one followed by hydrocephalus. The specimen from one case had already been presented to the New York Pathological Society, but at that time had not been examined microscopically. The method of treatment was that adopted by Morton, of Glasgow, and consisted of aspirating one or two drachms of the fluid and injecting iodoglycerine, the quantity injected varying from a half to a drachm. The solution used contained iodine, grs. x.; glycerine, ʒ j.; and iodine of potassium, ʒ ss. In both cases the sac was obliterated. Both children died not long afterward, one from hydrocephalus, and the other from cholera-infantum.

Dr. L. C. Gray, of Brooklyn, then read a paper on

THE USE OF STRYCHNIA IN NERVOUS DISEASES,

in which he reported several cases where he had administered strychnia, with special reference to the method brought forward by Dr. J. S. Jewell, of Chicago, at a previous meeting of the Association, namely, the use of large doses, as much, perhaps, as one-twelfth of a grain in myelitics.

Dr. Gray had used the drug in acute, subacute, and chronic cases, and in the acute and subacute it had aggravated or produced alarming or unpleasant symptoms when carried as high as one-twenty-fifth of a grain. In the chronic cases better results were obtained, but the largest dose he had felt warranted in employing had been one-twentieth of a grain. His experience, therefore, did not sustain the method recommended by Dr. Jewell.

Dr. C. L. Dana, of New York, had used strychnia in functional nervous diseases, in doses as large as one-eighth, one-sixth, and one-fifth of a grain three times a day, and with marked benefit. He thought there was no danger from either the accumulative or explosive effects of the drug which had been reported.

Dr. Seguin, of New York, thought that not much advance had been made with reference to the dosage of strychnia. Brown-Séquard many years ago advised and gave large doses repeatedly, as much as one-fifteenth of a grain three times a day in cases of functional disorder, and with no unpleasant effects, as a rule.

With regard to Dr. Jewell's cases, he had suggested that the reason why no unpleasant effects were produced by the large doses, was because the patients had no centrifugal matter with which to respond, as all of them were old cases of myelitis. Dr. Seguin, however, had not dared to carry Dr. Jewell's plan out thoroughly. He had been in the habit of giving the drug hypodermically.

Dr. Dana said he knew that Brown-Séquard had recommended large doses of strychnia, but he was not aware that one-fifth to one-sixth of a grain could be given three times a day without other than pleasant results, until he discovered it in the treatment of his cases.

The President then delivered his address, entitled

PARONOMY *versus* HETERONOMY AS NEURONYMIC PRINCIPLES.

For the term neurological nomenclature, Dr. Wilder uses the single word *neuronomy*. His general object has been to introduce a system of neuronomy, which, with a minimum of disturbance, in the existing order of things, may insure greater accuracy and brevity, and facilitate the acquisition and communication of knowledge between neurologists of all nations, to a considerable degree in the present, and to a much greater degree for our successors.

More specifically, the principal modifications proposed by him are indicated in the first publication on the subject in The Medical Record, September 18, 1880.

What he proposes and advocates is simply this: as far as possible for each part of the neuron (central nervous system), there should be found or made a name, consisting of a single Latin word, and that for each such Latin name, there be likewise found or made an English equivalent, not a translation, but a paronym, and furthermore, that in obtaining these names, due regard be had to existing nomenclatures, and established rules of etymological conversion.

Discussion was postponed until Friday.

The Society then went into executive session.

Third Day—Friday, June 19th—Afternoon Session.

The Association was called to order at 3 P.M. by the President.

Dr. E. C. Spitzka read a paper on

THE RELATIONS BETWEEN THE SYMPTOMS AND THE LESIONS OF POSTERIOR SPINAL SCLEROSIS.

The author closed his paper as follows: "While it must be admitted that the primary lesion of tabes is competent, for each affected level of the root zones and gray horns to produce all the characteristic symptoms of tabes referable to that level, yet in the extent and distribution of the consecutive lesions, we have valuable gauges of the extent, severity, and duration of the primary disturbance, and we may attribute to the following special disturbances the ensuing degeneration of the tracts whose functions are abolished or diminished: 1. That of the column of Goll to the disturbances of muscular sense in the lower extremities. 2. That of the

comma-shaped internal bands of the column of Burdach to the corresponding disturbances in the upper extremities. 3. That of the triangular area, bordering on the periphery of the cord, and the posterior root entry, to the rarer analgesic developments. 4. That of the column of Clark, and direct cerebellar (Fovill's) tract, to the disturbed space sense."

The paper was discussed by Dr. Seguin.

The President then presented a mounted specimen consisting of an injected preparation of the so-called circle of Willis, which illustrated

A SELDOM-DESCRIBED ARTERY.

(A. termatica), with suggestions as to the names of the principal encephalic arteries.

The communication was discussed by Dr. Starr.

Dr. Wilder also presented sections of brains illustrating

TWO LITTLE-KNOWN CEREBRAL FISSURES,

with suggestions as to fissural and gyral names.

Dr. Wharton Sinkler's (of Philadelphia) paper, entitled,

TWO CASES OF FRIEDREICH'S DISEASE,

was then read by Dr. G. B. Massey, of Philadelphia. Both cases lacked the congenital and hereditary history, and in neither had an autopsy been obtained.

The paper was discussed by Dr. Seguin, who referred to his paper on this subject, published in The Medical Record, June 13th, and also presented microscopic slides prepared by Dr. J. J. Putnam, of Boston, illustrating the changes found in the spinal cord in two of Smith's cases. In the study of the disease, he had been impressed with the fact of absence of pain and anæsthesia, associated with so extensive degeneration of the whole of the posterior columns and other portions of the cord.

Dr. Amidon, of New York, gave the clinical history of two cases of Friedreich's disease still under observation.

Dr. Starr, of New York, described the lesions as shown in the specimen from the case first observed by Friedreich. The changes were limited to the posterior columns, the pyramidal tracts, and the lateral columns and the tract of the cerebellar columns. The cord was also deformed, so that Friedreich considered it to be a congenital deformity.

The discussion was continued by Drs. Jacoby, of New York, Massey, of Philadelphia, and Amidon, of New York.

Dr. George W. Jacoby, of New York, presented

AN ABSOLUTE GALVANOMETER AND A RHEOSTAT

devised by Dr. J. Rudisch, of New York. The principle of the galvanometer was that first employed by Hirschmann, namely, a pair of astatic needles in a vertical instrument.

The advantages claimed for the rheostat over the ordinary water rheostat were lack of evaporation, no breakage, and no polarization.

The communication was discussed by Drs. Starr, Dana, G. M. Hammond, Birdsall, and Amidon, of New York, and Dr. Massey, of Philadelphia.

Dr. M. Allen Starr, of New York, then presented two series of

SECTIONS OF THE HUMAN BRAIN,

mounted by Dr. H. D. Schmidt, of New Orleans.

The Association then went into Executive Session.

Third Day—Friday, June 19th—Evening Session.

Dr. E. C. Spitzka, of New York, presented a specimen illustrating

A PECULIAR DEFORMITY OF THE CEREBELLUM,

produced by congenital lipomatosis. He also presented microscopic sections of the central nervous system of the cat, illustrating

GUDDEN'S ATROPHY METHOD.

Dr. B. G. Wilder, the President, presented a brain which illustrated

THE CONTINUITY OF THE DIACŒLIAN ENDYMA FROM THE MISAL SURFACE OF THE THALAMUS OVER THE HABENA TO THE DIATELE.

Also specimen illustrating

THE INSULA IN THE DOG, MONKEY, CHIMPANZEE, AND PORPOISE.

Dr. E. C. Seguin, of New York, then read a paper entitled

A CONTRIBUTION TO THE PATHOLOGY OF THE CEREBELLUM.

The case was one of tumor of the cerebellum occurring in A. M. B——, thirty-seven years of age, single, without syphilitic history, who came under Dr. Seguin's observation in consultation with Dr. English, of New Brunswick, N. J., in 1877. The autopsy was made April 24, 1885, by Dr. English and Dr. Elmer, of Trenton, N. J. Dr. Seguin had diagnosticated tumor of the cerebellum involving the superior vermis.

The symptoms were summarized as follows: Beginning with headache and one or more epileptoid or apoplectiform attacks; impaired vision, optic neuritis, and partial atrophy; typical cerebellar titubation, nystagmus; slight difficulty in articulation; no distinct paralysis; no ataxia; no anæsthesia; patellar reflex raised. Death with cerebral and bulbar symptoms, stupor, difficult articulation and deglutition, ptyalism, and polyuria.

Lesion.—Cyst of the cerebellum destroying the larger part of the vermis, penetrating the right lobe and pressing upon the floor of the fourth ventricle. Extensive syphilitic arteritis with varying forms of softening within the brain.

Dr. Amidon, of New York, reported a case in which there was found at autopsy a sarcomatous tumor involving the superior vermis, extending through the cerebellum, and destroying considerable of the floor of the fourth ventricle. The communication was further discussed by Drs. Gray, Spitzka, and Seguin.

Dr. J. K. Bauduy, of St. Louis, read a paper entitled

PHYSIOLOGICAL, PATHOLOGICAL, AND CLINICAL NOTES ON HYDROCHLORATE OF COCAINE.

The paper was chiefly interesting with reference to the author's claim concerning the efficacy of hypodermic injections of one grain of the alkaloid in the treatment of insanity, especially melancholia.

A paper by Dr. H. D. Schmidt, of New Orleans, entitled

A CASE OF DESTRUCTIVE LESIONS OF THE TEGMENTUM AND THALAMI, ETC.,

was read by title.

The President appointed the following

COMMITTEE ON ELECTRICAL DOSAGE,

to report at the next annual meeting: Drs. George W. Jacoby, R. W. Amidon, and W. R. Birdsall, of New York.

The Association then adjourned to meet, subject to the call of the Council, in June, 1886.

Cigarette Rollers' Cramp.—Dr. Torino has recently described a new form of professional cramp occurring in some workers in a cigarette factory. It affected the abductor and extensor muscles of the thumb.

M. Dujardin-Beaumetz has recently been made an officer in the Legion of Honor.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LATE SIR WILLIAM MUIR—REGIMENTAL SURGEONS—LORD WOLSELEY AND THE ARMY MEDICAL DEPARTMENT—AORTIC ANEURISM—THE GORDON MEMORIAL HOSPITAL AT PORT SAID—HARVEY'S LECTURE NOTES.

LONDON, June 6, 1885.

THE death of Sir William Muir, K.C.B., M.D., late Director-General of the Army Medical Department, breaks another link between the present and the last century. Educated at the University of Edinburgh, he was the pupil of Professor Syme, Sir Robert Christison, Sir Charles Bell, and Robert Knox, M.D., the anatomist. He took his M.D. at the early age of twenty-two, and entered the army as Assistant Surgeon two years later. He was nearly forty years on active service and served more than half of these abroad. Steadily gaining promotion he was appointed Director-General in 1874. An army surgeon of the old school, Sir William Muir passed through his career under the old system of regimental surgeons. When he became Director-General he took an active part in the abolition of the system under which he had himself served, and to him was entirely due the issue of the warrant of 1879 which established the Army Medical Department on its present basis. The medical officers are not now attached permanently to particular regiments, with which they always remain in the same manner as the combatant officers do, but form an entirely separate body, and can be sent anywhere where their services are needed. The change has not met with unqualified approval. Old army men allege that under the system of "regimental surgeons" the soldiers had more confidence in their doctors, because they were more intimately acquainted with them. The modern system of "short service" tends, however, to minimize this objection. An army may also chance to be left without its surgeons, as virtually happened in Egypt after the engagement of Tel-el-Kebir. Lord Wolseley gave orders that the transports containing the troops should weigh anchor and slip off from Alexandria under cover of night so as to surprise the enemy. No orders were, however, given to the Medical Department, which accordingly remained behind with the orderlies, bearers, and all appliances. I have been informed on competent authority that had it not been for the bearers and dhoolies of the Indian Contingent present, who worked well, many of the wounded must have been left upon the field. This could scarcely have occurred under the old regimental system, whatever its faults may have been. In talking over the above incident with an army medical officer of high rank and great experience I asked him plainly whether he did not think Lord Wolseley greatly to blame. He replied with grim humor: "Well, Lord Wolseley is Lord Wolseley." It may be remembered that "our only General" censured in no measured terms the Army Medical Department at the conclusion of the campaign, bringing charges against them which completely broke down in the course of the subsequent investigation.

I referred a few weeks ago to a case of aneurism which had been operated on by Mr. Pepper at St. Mary's Hospital. I now send a few more particulars. The patient was a laundress, and about thirty years of age. She was admitted into the hospital early in February last, having been suffering from symptoms only a few months. There was well-marked pulsation in the anterior thoracic region, and this extended up the right side of the neck. It was thought that this might be due to a diverticulum from either the carotid or innominate artery. There was dulness on percussion, but the dulness was almost entirely *on the left* of the sternum. There was well-marked dysphonia. The patient was kept in bed at absolute rest, the diet restricted, and iodide of potassium given in ten-grain doses every four hours. The dose was subsequently increased to twenty grains, under the influence of which an "iodide rash" appeared. The patient was one day suddenly seized with severe cerebral symptoms, viz., pain on the left side of the head, a sensation of "fire" in the left eye, and loss of sight in that organ. These symptoms went away in a few days and vision in the left eye returned. After a three-months' trial of rest, dietetic and medicinal treatment, an operation was consented to by the patient. The A. C. E. mixture was given, and the right carotid and subclavian arteries tied by Mr. Pepper, with antiseptic precautions. Pulsation in the right radial and superficial temporal arteries ceased immediately and did not return. Carbolized sponge was placed over the wound, then iodoform wool, and a bandage over all confining the arm to the side. The temperature did not rise above normal after the operation, and there was no suppuration. The "spray" was left off in a little over a week after the operation, and one of the ligatures came away in a fortnight. At the present date (a month after the operation) the patient is much improved, though not yet allowed to rise from bed. Pulsation is much less in the tumor and also in the neck.

The scheme for a Gordon memorial hospital at Port Said has been abandoned, as the site has been shown to be unhealthy. It is said that the committee literally jumped at this scheme simply because the Prince of Wales approved of it. Now that Port Said has been shown to be unsuitable, the Prince has readily withdrawn his recommendation, and the committee have found their tongues to say what they thought all along. The members of the committee seem to have been useless. They had better not have been appointed if they were afraid to open their mouths and say what they thought in the presence of the Prince of Wales.

An autotype reproduction is about to be issued of the original manuscript notes of William Harvey's lectures, delivered at the College of Physicians in 1616. In these lectures we find the first germ of Harvey's immortal discovery. A printed transcript is to accompany each page of the autotype reproduction.

THE PLYMOUTH EPIDEMIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A recent number of THE MEDICAL RECORD contains an article by W. J. Torrey, M.D., of Scranton, entitled "The Etiology of the Plymouth Epidemic," which was apparently written with so little knowledge of the conditions existing there, and is so misleading as to the agencies at work in producing the epidemic, that an explanation of the real facts seems called for.

In this article Dr. Torrey states that there were at least four factors which contributed "to the production and continuance of the epidemic." These were, "First, contaminated river-water; second, contaminated reservoir-water; third, contaminated milk; and fourth, contaminated air."

It is evident that Dr. Torrey has not visited Plymouth, and is not familiar with the water-supply there, or he could not have ascribed to the river-water such importance in the production and continuance of the epidemic as he has done. As has been pointed out several times before, there are in two localities on the hill above the town between forty and fifty families, who are supplied with water by the Hudson Canal & Coal Co. All of this water is pumped from the river, and these families have not used at any time anything but this river-water. Among them only two or three cases of typhoid fever have occurred, and the persons affected all drank reservoir-water in the town.

There is still further proof to show that the river-water took no part in the origin of the epidemic. As Dr. Taylor, of Wilkesbarre, has pointed out, during the period from March 20th to March 26th, when the larger part

of the town was supplied by river-water, a certain portion received all of its water-supply from the reservoir. When in Wilkesbarre a few weeks ago, while returning from Plymouth, Dr. Taylor showed me a map of Plymouth, in which he had carefully outlined the streets which had received river-water, and those which had received only reservoir-water. There was no difference in the distribution of the fever cases through the town, and in those portions which received all of their water-supply from the reservoir the fever appeared as early, in as severe a form, and proportionately as large a number of cases occurred as in those parts where the river-water was used from March 20th to 26th.

More than this, a number of cases of typhoid fever occurred in families living along the stream below the reservoirs who dipped water from the stream produced by the overflow from the reservoirs.

Can any further proof be required to exclude absolutely the use of river-water as supplying any factor either in the production or continuance of the epidemic?

As to the action of the contaminated reservoir-water in causing the outbreak, there cannot be the slightest doubt. All the physicians who have visited Plymouth for the purpose of investigating the cause of the epidemic are unanimous on this point, and regard it as being the sole *exciting* cause of the outbreak. All the facts connected with the conditions existing at Plymouth and the appearance of the epidemic, point so strongly in this direction that this conclusion is unavoidable. Undoubtedly other factors have been active in contributing to the continuance of the disease, such as contaminated well-water, contact with the sick, the lack of proper precautions as regards disinfection of the stools, etc.

As regards the third factor, namely, contaminated milk, it seems rather absurd to ascribe much importance to the effects of drinking milk that is possibly diluted with contaminated water, when this same water is being constantly used for all purposes.

Certainly the second method of contaminating the milk suggested by Dr. Torrey—*i.e.*, "through the cows drinking the contaminated water, the poison being excreted with the milk"—is a new one. Dr. Torrey says, "There is no reason to believe that the specific element in the production of typhoid fever goes to play a part in the economy of the cow; but it is reasonable to suppose that in circulating through the body it might contaminate the secretions of the animal, although unable to produce its specific effects on it" [the cow].

There can be no doubt that the specific element in the production of typhoid fever is a micro-organism, and it is certainly assuming a good deal to say that this germ may be received by the cow in contaminated water, may pass into the blood without producing any effects on the animal, then be secreted with the milk, and finally produce typhoid fever in persons drinking the milk. I think that this scarcely needs further comment.

It is quite probable, as has been already pointed out, that the contamination of the air has had some influence in the continuance of the epidemic, but, of course, none in its production.

We are driven back now to the original conclusion, namely, that the contamination of the reservoir-water by the stools of a single case of typhoid fever situated on its bank was the sole exciting cause of the epidemic at Plymouth. Respectfully yours,

HERMANN M. BIGGS, M.D.

21 EAST TWENTY-FIRST STREET, NEW YORK, June 10, 1885.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Four cities and one medical society have sent committees of medical men to Plymouth to investigate the cause of the outbreak of a thousand cases of typhoid fever, which occurred in that town last April, and all have come unanimously to the same conclusion; namely, that it had its origin in the contamination of the mountain stream with the accumulated excreta of a typhoid patient which had been washed into it when the spring thaw occurred.

Dr. Torrey, however, writing from the seclusion of his office, without having gone over the ground, and apparently without having all the facts before him, comes to a different conclusion. Instead of one factor he finds four, the contamination of the mountain stream water being one of them, but "by no means the most important one."

I have these objections to make to Dr. Torrey's method of arriving at his conclusions: first, he fails to take cognizance of all the facts; second, he misstates facts; third, his own peculiar conclusions, notably numbers three and four, are unsupported by a single fact.

Take, for example, his conclusion that contaminated milk played an important part in the causation. Instead of adducing a single fact tending to show that a single person of the thousand could even be suspected of having taken the disease by drinking contaminated milk, he reasons as follows:

Typhoid fever is sometimes caused by drinking milk.

Presumably, Plymouth people drink milk.

Therefore contaminated milk was a factor in the causation of the Plymouth epidemic.

Without pointing out in detail the errors and misstatements contained in the Doctor's paper, I will say generally, that too many of his premises are wrong; but, even if they were right, his conclusions would not follow logically.

As it seems to me extremely desirable that a correct conclusion should be arrived at on this subject, I beg leave to submit to your readers some of the principal facts and arguments which have led so many investigators to adopt this so-called mountain-stream theory.

First.—There is the great fact, clearly established, that the accumulated excreta of a typhoid patient were actually carried into the stream when the spring thaw occurred, which was about April 1st.

Second.—Following this, after a period corresponding in length to that which has generally been recognized as the usual period of incubation of typhoid fever, an outbreak of a thousand cases of the disease occurred in the town.

Third.—These cases occurred only in those who used hydrant-water; those using well or other water exclusively escaping altogether.

But it is also true that from March 20th to 26th water from the river was pumped into the mains supplying the town, and the necessity of showing why this water may not have been at fault instead of the mountain-stream water, has been fully recognized by all the investigators.

The difficulties in the way of accepting the river theory, so-called, are many and, it seems to me, insuperable. Let me present a few of them.

1. It remains to be proven that the excreta of a single typhoid patient did actually find its way into the Susquehanna above Plymouth, during the month of March.

2. Admitting that there were some cases in the valley during that month, the frozen condition of the river and its tributaries would effectually prevent any excreta from getting into the river except through the sewers.

3. Admitting that excreta from fever patients did get into the river from the Wilkesbarre and Pittston sewers in March (which is not proven), yet, in view of the large body of water which is always present in the river, and that only such a small fractional part of this could find its way into the water company's pipes, and the fact that any contaminating material which may get into a running stream must all necessarily pass a given point in a very short time, it would seem that the objection of infinitesimalism which has been urged against the mountain-stream theory, applies with tenfold force to the river theory.

4. The time from March 20th to April 10th, when the first case of the epidemic occurred, is too long for what has generally been recognized as the usual period of incubation of typhoid fever.

5. That the excreta from the cases of fever which occurred in Pittston during the fall months could so pollute the river as that it should continue to retain its poison through all the winter months, and that in the last days of March it should possess a degree of virulence sufficient to produce one of the most extraordinary epidemics on record, seems to me highly improbable, especially in view of the fact that in the last week of December there was a great break-up and flood in the river, which lasted for many days.

6. But if river-water was so poisonous from March 20th to 26th as to cause a thousand cases of fever in those who used water obtained at one point in the river, it is difficult to understand why the inhabitants of Broadway and Ridge Row, a portion of Plymouth supplied during all the winter months and until April 1st with water pumped from the river at a point half a mile higher up the stream, should escape the fever altogether, the fact being that not a case has yet appeared among these people, numbering several hundred souls.

7. Again, if river-water was so poisonous in March, it is difficult to understand why Nanticoke, a town of eight thousand inhabitants, situated three miles below Plymouth, and which is supplied all the time with river-water, should not only be exempt from epidemics, but should be freer from typhoid fever during March and April than during any months of the past year.

8. But the considerations which bear with the greatest force as against the river theory, and in favor of the mountain-stream, and which seem to me to be conclusive on the subject, are derived from the histories of twelve cases of the fever, collected by Dr. Taylor, occurring in persons who moved to Plymouth between March 30th and April 5th, inclusive, and whose first opportunity, therefore, to drink Plymouth water occurred between these dates, this being from four to ten days after pumping from the river had ceased. Again, these twelve persons, who could not have possibly used river-water, began to be sick with the disease within the same period of time that the great majority of the other thousand cases were taken, viz., the first on April 12th and the last on April 22d.

The earliest case of the epidemic occurred on the 10th, but a great many occurred after the 22d. This latter fact, however, only serves to strengthen the conviction that the river-water could not have been the cause. Again, the period of incubation in these twelve cases, counting from the first day that they had an opportunity to drink Plymouth water, was from ten to eighteen days.

The period cannot be longer than this, but may be shorter, as it is impossible to tell how long after their arrival the fatal draught was taken. Now, ten to eighteen days being thus shown to be the longest possible period of incubation in these twelve cases, I leave all to judge how far we are justified in concluding that the period of incubation was of the same duration in all the other cases.

But, again, it being thus shown that in this epidemic the period of incubation in at least twelve cases was from ten to eighteen days, it is incumbent upon the advocates of the river theory to show why it is that not one single case of the thousand was taken ill in either ten or eighteen days from March 20th, when river-water began to be used, or even in less than sixteen days after March 26th, when the use of river-water ceased. The difficulty of accounting for this fact becomes greatly enhanced if it be true, as Dr. Torrey claims it is, that the period may be as short as three days.

These are some, though by no means all, of the facts and considerations upon which the opinion is founded that the washing into the stream of the excretion of poor David Jones was the great active cause of the epidemic, the one factor without which this terrible scourge would not have had an existence.

R. Davis, A.B., M.D.

Wilkesbarre, Pa., June 13, 1885.

Report of Committee on Disinfectants.—Dr. J. H. Raymond, of Brooklyn, N. Y., writes: "I notice in your issue of June 6th a criticism signed by J. R. Duggan, M.D., Ph.D., and C. T. McClintock, A.M., on the 'Preliminary Report of the Committee on Disinfectants of the American Public Health Association.' In the absence of Dr. Sternberg, the Chairman of the Committee, who is now in Europe attending the International Sanitary Conference, I will simply say that the writers of the criticism have evidently not seen the Committee's Report published more than a month ago; their observations are evidently based upon a former edition of the 'Preliminary Report.' In regard to the non-existence in the market of a solution of chlorinated soda containing at least three per cent. of available chlorine, the amount required for disinfection, I would say that Dr. Squibb, of Brooklyn, has a preparation containing six per cent. I regret that an answer to this communication is called for at this time when the Chairman of the Committee is absent, and feel that had the proper inquiry been made of the Secretary of the Committee, this 'criticism' would not have apeared in your journal. Copies of the report can be obtained by sending to Dr. Rohé, Baltimore, Md."

Early Medical Ethics.—To those, says the *Columbus Medical Journal*, who are fond of referring to the "good old times" the following slip, found the other day in an old copy of *Abernethy's Surgery*, may be of interest: "Dr. J. Heilbronn, late of the city of Philadelphia, has the honor to announce to the public that he has, in conjunction with Dr. Lobstein, commenced the practice of medicine in the town of Reading, and cherishes a hope that from his knowledge of the science of medicine, and his will to put it into practice and render justice and satisfaction to those who may need his assistance, he will merit a moiety of public patronage. Dr. Lobstein is a practitioner of great experience, and of known and acknowledged skill and abilities, both in Europe and America, which he is ready to verify when thereunto required. His private character may be objectionable (who is perfect?), but as a physician he stands unimpeached, and I trust that a generous and enlightened public will not condemn him untried or unheard.—J. Heilbronn, July 6, 1821."

INDEX.

A

Abdominal section, 1.
Abortion, 493; due to reflex irritation, 39; missed, 78; mistaken for menorrhagia, 84.
Abscess, aspiration of, 498; cold, 558; of the liver, 23, 261, 348, 359; of the testicle, 385; parametritic, 493; pelvic, 153.
Accoucheur, the, and sepsis, 493.
Acid, benzoic, 209; carbolic, disinfectant action of watery solutions of, 607; carbolic, for dysentery, 432; dilute sulphuric, 300; lactic, in the destruction of new growth, 515; osmic, in neuralgia, 713; sulphurous, 364; tartaric, 475.
Acne, 474.
Aconite, against neuralgia, 402; poisoning by, 195, 245, 364.
Actinomycosis, 588; not a new disease, 712.
Adamson, Dr. W. R., extraction of hair-pins from the uterus and rectum, 68.
Adenoma of the ovary, 441.
Advertising, professional, 689.
Æsthesiometry, 247, 230.
Air of operating-rooms, purification of, 464.
Albany Hospital, 347.
Albumin, in the urine, 308; tests for, 369.
Albuminuria, 219; and ovariotomy, 336; in syphilis, 585.
Alcohol, for parturient women, 55; in the treatment of insanity, 297.
Alcoholic paralysis, 516.
Alcoholism, cocaine in, 321.
Alderson, Dr. M. E., cocaine, 374.
Alexander's operation, 445.
Allen, Dr. Harrison, notice of book by, 215.
Allen, Dr. H. N., correspondence, 671.
Allport, Dr. Frank, peroxide of hydrogen in aural therapeutics, 541.
Aloes, 300.
Alumni Association Prize of the College of Physicians and Surgeons, New York, 712.
Alum, 242.

Ammonia, benzoate of, 368; carbonate of, in scarlet fever, 318; chloride of, 364; citrate of, 242; nitrate of, 271; muriate of, 280.
Ammoniac, gum, with camphor, 289.
Amputations, 332.
Amyl, nitrite of, 293.
Anæmia, idiopathic, 485.
Anæsthesia, local, of the integument produced by cocaine, 69; rapid, 499.
Anæsthetic, local, cannabis indica as a, 195.
Anæsthetizing, a new method, 392.
Analysis, novel urinary, 26.
Andrews, Dr. Joseph A., malarial affections of the ear, 277.
Aneurism, abdominal, 526; of the abdominal aorta, 23; of the popliteal artery, 374; of abdominal aorta cured by laparotomy, etc., 628; of splenic artery, 597; thoracic, galvano-puncture in, 379.
Aneurisms, popliteal, 404.
Ankle, resection of, 606.
Anthrax, 463; dry cupping for, 68.
Antipyresis, 585.
Antipyretics, 308.
Antipyrin, 280, 322, 413, 476, 581, 657; in phthisis, 629; in pneumonia and other febrile diseases, 373.
Antiseptic precautions, 392; treatment of pulmonary disease, 57.
Antivaccination, 73.
Anus, artificial, 558; artificial, cured by enterotomy, 349.
Aorta, abdominal, aneurism of, 23.
Aphasia, from fright in a child, 629.
Apiol, 588.
Apomorphine, 121.
Apoplexy, unusual cases, 360, 371.
Apothecaries, the duties and responsibilities of, 266.
Arsenic, 224; in articles of domestic use, 72; poisoning from, 145.
Arteries, atheromatous degeneration of the, 443; healing of, after ligation, 468; sclerosis of the coronary, 597.
Artery, inflammation of the pulmonary, 433; bronchial, thrombosis of the, 208.
Ascaris, vermicularis, 117.
Ascites, chyliform, 39.
Asphyxia, from ether, 245.
Aspirator, the use of the, after tracheotomy, 96.
Asthma, 95, 323, 585; Himrod's cure, 308; surgical treatment of, 584.
Astragalus, resection of the, 556.
Asylums, fire in insane, 212.
Ataxy, early signs of, 322; family, 645; spinal, 657.
Atkinson, Dr. George H., notice of death of, 18.
Atropia, and morphia, 514; in electric shock, 120; in ether-narcosis, 477; *vs.* morphia in morphia-poisoning, 531.
Atropine-poisoning, 235.
Auscultatory percussion, 600.
Autophonia, 513, 520.

B

Bacillus, of syphilis, 73, 381, 435; of tubercle in the urine, 41; of tuberculosis, 516; the cheese, and cholera, 185.
Bacon, Dr. Gorham, traumatic lesions of the membrana tympani, 403.
Bacteria, from the soil to the air, 280; in ordinary drinking-water, 404; number in the air, 336.
Bacteriology, 172.
Baker, Dr. A. H., scarlet fever, 531.
Baker, Dr. B. O., tape-worm, 475.
Baker, Dr. J. E., cocaine in teething of infants, 181.
Bantock, Dr. George G., book notice, 132.
Barclay, Dr. Robert, hospital notes, 513.
Barker, Dr. C. F., alcoholic hyperæsthesia of the feet, 402.
Barker, Dr. Fordyce, 18, 462; address, 141; presentation of portrait of, 469.
Barometer in the coffee-cup, 528.
Baths, prolonged, 377.
Beach, Dr. R. E., rhinoliths, 706.
Bean, Dr. E. A., impotence and hernia, 260.
Belfield, Dr. W. T., book notice, 271.
Benedict, Dr. A. C., 208.
Bennett, Dr. W. H., hot water and hemorrhoids, 532.
Benton, Dr. A. W., delirium tremens in a boy three years old, 643.
Benzoin, inhalation of the tincture of, for nasal catarrh, 552.
Biggs, Dr. Hermann M., Plymouth epidemic, 717.
Bile, secretion of, 124.
Binkerd, Dr. A. D., compound dislocation of the tibia, 515.
Bismuth, for dressing wounds, 224; test for sugar, 196.
Blackwell, Dr. E., the new treatment of gonorrhœa, 261.
Bladder, carcinoma of the, 329; digital examination of, 669; dilatation of, in incontinence of urine, 686; exploration of, 665; irritable, 123, 533; papilloma of the, 531; removal of tumors from, 281.
Blaisdell, Dr. Albert F., book notice, 440.
Blake, Dr. Sophia Jex, book notice, 271.
Bleyer, Dr. J. Mount, tongue-depressor with electric light, 699.
Blisters in pneumonia, 546.
Blood, inhalation and injection of, 408.
Board of Medical Examiners, 156.
Bodenhamer, Dr. William, notice of book by, 104.
Bones, polyuria in diseases of, 557; tuberculosis of, 605.
Bone-setter, the, and the boy, 168.
Bopp, Dr. Louis, obituary, 300.
Bougies, horse-hair, 474.
Bovine vaccination, dangers of, 363; virus, necessity for pure, 420.
Bowels, impaction of, 616.
Bosworth, Dr. F. H., sarcoma of the nares and vault of the pharynx, 62.
Bradbury, Dr. S., therapeutic value of iron given alone, 193.
Bradner, Dr. William B., posterior luxation of the forearm, 319.
Brain, circulation of, influenced by electricity, 164; glioma of the, 541; limitation of the surgery of the human, 465; method of staining large sections of the, 164; nomenclature, 709; sarcoma of the, 359; sensory tracts in the, 631; successful removal of a tumor from, 45.
Bramwell, Dr. Byron, notice of book by, 104.
Brannan, Dr. J. W., 672.
Breast, carcinoma of, 273; recurrent fibroma of, 302.
Bright's disease, acute, treatment of, 12; heredity in, 685.
Broncho-pneumonia as a complication of diphtheritic croup, 108.
Brooks, Dr. C. G., queen of the meadow for enlargement of the prostate, 364.
Brown, Dr. Judson C., dry gangrene, 374.
Brown, Dr. J. Graham, notice of book by, 76.
Brown, Dr. W. B., cocaine in neuralgia, 180.
Browning, Dr. A. G., a new habit, 452.
Brush, Dr. E. F., intubation of the larynx, 206; traumatic gastric fistula, 623.
Burgess, Dr. F. N., pregnancy in a woman fifty-one years old, 280.
Burns, simple treatment of, 700.
Button-hook as an eye-opener, 475.

C

Cæcum, epithelioma of, 336; excision of, for epithelioma, 459.
Cæsarean section, 528.
Caffeine, in heart disease, 292; local application of, to the conjunctiva, 644.
Caries, spinal, 639.

Cahill, Dr. H. H., fracture of the radius in a woman seventy years of age, 69.
Calculus, salivary, 218.
Calls, excuse for delayed, 195.
Calomel in acute lobar pneumonia, 204; in cholera, 123.
Camden, Dr. T. B., hysteria, 375.
Campbell, Dr. S. E., thrombosis of the bronchial artery, 208.
Cancer, alleged increase of, 296; encephaloid, and scirrhus, 41; hysterectomy for, 41; in Baltimore, 463; in horses, 167; inoculation, 531; new cure for, 102; of the peritoneum, 386, 539; of the tongue, and smoking, 381; of the testicle in infants, 707; parasitic origin of, 436; prevalence of, 193; recent contribution to the study of, 325; the pathology of, 71; treatment of, 518.
Cancer-cures, 407.
Cannabis indica, 474; as a local anæsthetic, 195.
Capsicum in the treatment of anal fissures, 684.
Carbuncle, 491.
Carcinoma, and syphilis, 293; of the bladder, 329; of the breast, 273; of the ovary, 358.
Caries, dental, causes and prevention of, 14.
Carpenter, Dr. J. S., septicæmia following the human bite, 482.
Carpenter, Dr. H. W., evacuation of ovarian tumor through the intestines, 672.
Carr, Dr. Walter L., correspondence, 278; gonorrhœal ophthalmia, 317.
Carroll, Dr. W. H., aneurism of the popliteal artery, 374.
Cary, Dr. Frank, 348.
Cataract, law of heredity of, 97; new operation for, 154.
Catarrh, intestinal, 137; nasal, 284; nasal, tincture of benzoin for, 552; with reference to deviated septum, 301.
Catheterization, telescopic, 207.
Cerebellum, contribution to the pathology of, 715.
Chambers, Dr. M. L., scarlet fever, 392.
Chancre, excision of, 97; of the eyelids, 405.

Electricity as a stimulant in cardiac and respiratory failure, 245.
Electro-puncture in lead palsy, 377.
Elliott, Dr. George R., General Grant's throat, 289.
Elsberg, Dr. Louis, obituary, 242; resolutions, 438.
Ely, Dr. Edward Talbot, notice of death of, 438; resolutions, 588.
Epilepsy, Jacksonian, 124.
Embolism, 497.
Emmet's operation, 494, 554.
Empyema, 649; accidental loss of drainage-tubes in the pleural cavity, 3; excision of a rib for, 540.
Encyclopædia of Surgery, International, book notice, 103.
Endocarditis, 573; ulcerative, 362.
Endocervicitis, 504.
Endometritis fungosa, 449, 470.
Enteritis, toxic, 290, 689.
Enterotomy, for artificial anus, 349.
Entropion, 181.
Enuresis, 701.
Epidemic fund, 126.
Epidemics, sanitary importance of, 42.
Epilepsy, sensory, 365.
Epipedometer, 201.
Epithelioma, from long-continued irritation, 357; of the cæcum, 336, 459; of the larynx, 480; of the leg, 274; of the tonsil, 262; of the tongue, operation for, 351.
Ergot, chemistry and therapeutical properties of, 268.
Ergotine and pilocarpine, 686.
Erichsen, Dr. Hugo, book notice, 691.
Erichsen, Mr. John Eric, notice of book by, 215.
Erigeron for leucorrhœa, 499.
Erysipelas, 334; a complication of pregnancy, 124; etiology of, 641; following incision in the skin for the relief of anasarca, 274; inoculation, 323.
Ether, as an anæsthetic, 332; asphyxia from, 245.
Ethics, early medical, 717; interpretations of the Code, 490; of placebos, 460.
Eucalyptus in the treatment of typhoid fever, 597.
Eve, Dr. Edward J., the microphone in physical diagnosis, 430.
Excision, the question of, 332.
Exophthalmic goitre, 471; and blond hair, 700.
Expert testimony, value of, 183.
Eye, and gout, relations between, 196; diseases of, and gout, 40.
Eyelids, chancre of, 405.
Eyesight affected by digitalis, 432.
Eye-speculum, 392.

F

Fallopian tubes, diseases of, 85, 105.
Faulkner, Dr. Richard B., the cure of asthma, 95.
Feeding without forcing, 56.
Feet, alcohol hyperæsthesia and paræsthesia of, 402.
Femur, injuries and fractures of the neck of, 511; osteitis of the upper extremity of, 77.
Fenn, Dr. C. M., intestinal strangulation, 308.
Ferrán, honors to Dr., 532.
Fever, breakbone, 122; Dr. Fordyce's treatment in, 1766; incubation of scarlet, 445; intermittent, inoculation of, 320; malarial, pathology of, 484; malarial, retinal hemorrhages in, 705; scarlet, 304, 531, 612; scarlet, can it be communicated by a third healthy person? 353; scarlet, carbonate of ammonia in, 318; scarlet, communicability through a third person, 541; scarlet, contagiousness of, 392; scarlet, the contagion of, 447; typhoid, 573; typhoid, early diagnosis in, 685; typhoid, eucalyptus in, 597; typhoid, in children, 409; typhoid, perforation of the bowel with recovery, 38; yellow, 411.
Fevers, acute infectious, 304.
Fibroma, recurrent, of the breast, 302; parasitic, of the skin, 432.
Finch, Dr. Rodney G. D., notice of death, 547.
Fingers, save the, 196.
Fissures, anal, capsicum in, 684.
Fistula, fecal, after ovariotomy, 636; vesico-uterine, 119.
Fliesburg, Dr. O. A., the bismuth test for sugar, 196.
Flynn, Dr. J. W., 349.
Foods which do not favor the growth of the comma bacilli, 224.
Foramen ovale, persistence of, 432.
Forearm, fracture of, 640; malformation of the, 220; posterior luxation of, 319; ununited fracture of, 69.
Forceps, fenestrated cartilage, 167; hemostatic, 192; obstetric, 551.
Form-blindness, 130.
Fowler, Dr. George B., sugar in the urine, 482.
Fracture, of the base of the skull, 661; of the forearm, 640; of the patella, 557; of the radius, 69; ununited, of forearm, 69; spontaneous, 433.
Fractures, 492; compound, treated by wiring and drainage, 553; false doctrines in the treatment of, 553; local extension in, 425; non-union of, 332.
French Surgical Congress, 556.
French Association for the Advancement of Science, 711.
Friction sounds, valvular, 429.
Friedreich's disease, 645.
Frost, Dr. C. C., correspondence, 419.
Frost, Dr. L. A., a vaginal douche, 252.
Funis, reduction of, 542.

G

Gaillard, Dr. E. S., notice of death of, 151.
Gall-bladder, surgery of the, 13.
Galvanism in the treatment of extra-uterine pregnancy, 65, 79.
Galvanometer, the absolute, 247.
Galvano-puncture in thoracic aneurism, 379.
Gangrene, dry, of fingers, 122; from a hypodermic injection of quinine, 196; of the lung following primary pneumonia, 21; symmetrical dry, 349, 374.
Gastritis favosa, 46.
Gastro-enteritis favosa, 629.
Gastrotomy, 558.
Gatchell, Dr. Edward A., the climate of North Carolina for consumptives, 54.
Geddings, Dr. W. H., the climate of South Carolina, 28.
Geography and medical science, 689.
Geometry, anatomical, 528.
Geometry and toponymy, anatomical, 197.
German Congress of Internal Medicine, 585.
German Surgical Society, 604.
Germicides, 70.
Geroke, Dr. R. O., 644.
Gilliam, Dr. D. Tod, rapid dilatation of the uterine canal, 511; transfusion of milk in opium-poisoning, 679.
Giving the young man a chance, 279.
Glaucoma, stretching the external nasi nerve for, 504.
Glioma of the brain, 541.
Glycerine as an excipient, 65.
Glycosuria, 393.
Godfrey, Dr. John, 28.
Goff, Dr. J. N., chlorine battery, 224.
Goitre, exophthalmic, 471; successfully treated with iodine, 38; the treatment of, 26.
Goldmann, Dr. Edmund, catarrhal enteritis and dysentery, 137.
Gonorrhœa, 529; the new treatment of, 261.
Goodheart, Dr. James Frederick, notice of book by, 523.
Gorgas, Dr. F. J. S., book notice, 243.
Gould, Dr. A. Pearce, book notice, 243.
Gout and the eye, relations between, 40, 196.
Granular lids, jequirity for, 180.
Grant, the General's condition, 213, 267, 270, 295, 326, 352, 381, 410, 435, 461, 520, 575, 710; at Shiloh, 223; specimens from the General's throat, 289.
Greene, Dr. William H., ureameter, 465.
Grinnell, Dr. A. P., correspondence, 362.
Groom, Dr. W. S., sugar in the urine, 69.
Grove, Dr. H. B., cocaine in eye practice, 181.
Gynæcology, 417.

H

Hadden, Dr. Alexander, a remedy for the manure nuisance, 26.
Hall, Dr. Julia Townsend, roller-skating, 669.
Hæmoglobinuria and syphilis, 40.
Hæmoptysis, tincture of matico in, 529.
Hair, superfluous, 568.
Hall, Dr. Egbert A., laryngo-thyotomy, 319.
Hall, Dr. George Newell, urethral spasm relieved by cocaine, 318.
Hamilton, Dr. Allan McLane, sensory epilepsy, 365.
Hamilton, Dr. Frank Hastings, lacerated perineum, 676; notice of book by, 104.
Harlem Medical Association, 79.
Harlingen, Dr. Arthur van, notice of book by, 132.
Hart, Dr. A. Henri, hypodermic syringe, 224.
Hartigan, Dr. J. F., notice of monograph by, 215.
Hassall, Dr. Arthur Hill, notice of book by, 384.
Hay asthma, 583.
Health bill, the new, 19, 139.
Heart, a large (weight forty-four ounces), 37; auricular and ventricular movements, 379; Broadbent on disease of, 276; bullet-wound of, 380; bullet-wounds of, 510, 626; digitalis in valvular disease of the, 335; hypertrophy of, 707; voluntary acceleration of, 700; wounds of the, 527, 643.
Helenine, 377.
Hematocele, pelvic, 517, 635.
Hematoidin, peculiar form of crystals of, 441.
Hemianæsthesia, 49.
Hemiplegia, double infantile spastic, 125.
Hemorrhage, intracranial, in children, 133; post-partum, 280; submucous laryngeal, 317; uterine, 377.
Hemorrhoids and hot water, 532.
Henderson, Dr. Thomas J., calomel in cholera, 123.
Herb-doctors' paradise, 700.
Heredity in Bright's disease, 685.
Hermance, Dr. E. M., 208.
Hernia and impotence, 265; in the infant, 314; strangulated, 9, 319, 504, 526.
Herpes zoster, 264; is it contagious? 97.
Hewetson, Dr. A. H., scarlet fever, 541.
Hiccough cured by jaborandi, 336.
High buildings and public health, 408.
Hillbish, Dr. F. S., the malignancy of syphilis, 74.
Hinde, Dr. Alfred, paralysis of the iritic muscles, 455.
Hip, congenital dislocation of the, 574; resection of, 558.
Holden, Dr. Luther, notice of book by, 440.
Holt, Dr. L. Emmet, irregular manifestations of malaria, 591; pneumonia in young children, 174, 201, 217.
Homans, Dr. John, the spray in ovariotomy, 364.
Horse-hair sutures and drainage, 05.
Horwitz, Dr. Lloyd Norris, typhoid fever with perforation and recovery, 38.
Hospitals, examinations for, 546; for shop-girls, 100; moneys for, 214.
Howard, Dr. Benjamin D., cholera in France, 93.

How shall the physician wash his hands? 632.
Huber, Dr. F., drainage-tubes accidentally lost in the pleural cavity, 3.
Hudson, Dr. E. Darwin, Jr., limitations of the diagnosis of malaria, 617; the physical examination of weak chests, 505, 551.
Hughes, Dr. C. H., cocaine, 68.
Hulse, Dr. W. A., puerperal eclampsia, 515.
Hunt, Dr. S. H., septic pyæmia before parturition, etc., 8.
Hunter, Dr. C. H., passage of a tooth-plate through the pylorus, 644.
Hunter, Dr. James B., endometritis fungosa, 449, 470.
Hurd, Dr. S. H., strangulated hernia, 319.
Husband, Dr. H. Aubrey, book notice, 692.
Hutchinson, Dr. Mahlon, tolerance of large doses of iodide of potassium, 190.
Hutton, Dr. T. J., diphtheria, 672.
Hydrocele, tapping for, followed by suppuration, 385.
Hydrocephalus, primary, in the adult, 331.
Hydrosalpinx, 273, 357, 358.
Hydrochinon, a new antipyretic, 593.
Hydrology and climatology, 476.
Hydrogen, peroxide of, in aural therapeutics, 541.
Hypodermic syringe, 224.
Hysterectomy for cancer, 41.
Hysteria, 375.
Hysterotomy for "pin-hole os," 628.

I

Illinois State Medical Society, 579, 607.
Imbedding process for microscopic work, 429.

A CASE OF CYSTIC TUMOR OF THE JAW IN A NEGRO, AND SOME NEW OBSERVATIONS ON THE PATHOLOGICAL HISTOLOGY OF THIS DISEASE.

BY AUGUSTUS C. BERNAYS, A.M., M.D. HEIDELBERG; M.R.C.S.E., F.R.M.S. LOND.,

MEMBER OF THE GERMAN SOCIETY OF SURGEONS OF BERLIN; PROFESSOR OF ANATOMY OF THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

THE patient, W. G——, a full-blooded negro, about twenty years of age, was brought to me about October 1, 1884, by Drs. Skeele and Robinson, of Harrisonville, Ill. Fig. No. 1 shows his condition at that time. He was

FIG. 1.

in every way well developed, perfectly healthy, had never been seriously sick. He stated that his jaw had been slowly growing larger and more protruding for about two years. There had never been any severe pain during its growth, and it only troubled him recently on account of its large size, and because it now prevented him from closing his mouth entirely. There was considerable hypersecretion of saliva, which would be thrown from his mouth while speaking, and would continually overrun the corners of his mouth. His speech was but little disturbed by the tumor, the tongue being as yet quite free and movable. The teeth in the lower jaw were not in their proper positions. Some had been previously lost; in fact, only the two last molars were present on the right side, and only the præmolar on the left. The four incisors and the two canines were still present, but not in line. The teeth were all normal, except the second molar on the right side, which showed a deep cavity in its posterior median root. The teeth were all quite loose in their sockets. The eruption of the teeth, so far as known to the patient, had been normal. He had suffered considerably from toothache, and had lost the missing teeth by extraction, on account of the pain they gave him. He states that the growth of the tumor began soon after the extraction of the first right molar tooth, and believes that all his trouble came from this tooth. We shall see later on that very probably the growth of the tumor began previous to his toothache, and perhaps even caused his dental trouble.

The tumor was found to be nearly five inches in its largest diameter from right to left, a little below the line of the mouth. Its thickness from the chin to the alveolar process was about two and three-fourths inches. The tumor extended almost to the coronoid process, involving the entire body and a portion of the ascending ramus on both sides. It was almost regular in its form, showing only slight lumpy enlargements on its surface. The tumor was quite hard in some places, while in others the cystic growth had distended the jawbone so much that a crackling, as if of parchment, was conveyed to the examining finger. Some of these thinnest places were clearly fluctuating and almost translucent. The skin of the chin was very smooth, and the skin of the cheeks and neck was drawn out, as was also the lower lip, in order to cover the tumor. Little or no growth of beard was noticeable on the distended skin. There was no communication of any of the cysts with the cavity of the mouth; percussion over the tumor was dull (see Figs. 4 and 5).

Before describing the operation and its results, I will give a short *résumé* of what is known up to the present day about the cystic degenerations of the lower jaw, and finally describe the pathological histology of my case, comparing it with the observations of my fellow-workers in this field of research. A complete list of the literature used by me in this study will be found attached.

In the entire literature of this subject I have found the histories of 122 cases of tumors of the jaw, some of which are very accurately described, and others are only reported very briefly. In an attempt to tabulate them I found it thankless work, since many of the points which command our consideration were overlooked or imperfectly stated. Thus, for instance, the minute structure is not known of over 90 cases. In fact, I can only find reports of 24 cases that have been properly examined by the microscope. Instead of detailing these 122 cases singly I may be permitted here to give their description in a general way. Magitat has compiled 100 cases, and I must refer any one especially interested to his work (op. cit.).

These tumors have been variously called multilocular cystic tumor, adeno-sarcoma, cysto-sarcoma, jaw cysts, cysto-maproliferum maxillæ, follicular cystoma, cysto-fibroid, cysto-dermoid, and lastly, Mr. Eve has proposed for them the name of multilocular cystic epithelial tumor (*cystoma multiloculare epitheliale*). It will be seen that these names may cover a multitude of pathological formations of the jaw. The fact of there being so many different names points out that some real difference probably exists between these cystic tumors. The only correct course to follow in naming pathological formations seems to me to be based on an accurate investigation of their development or evolution. I will therefore defer the christening of my tumor until after we shall have considered its histo pathogenesis.

The disease is rarer in the upper jaw than in the lower,

the ratio being in my table as 1 to 11. The tumors vary in size from a pigeon's-egg to the size of a large head. They grow within the bone, expanding the compact outer layer, so that it forms a bony capsule of varying thickness around them. Fig. 5 will give a good idea of a section. There is a conglomeration of cavities of various sizes appearing like an irregular honeycomb. The cysts are separated by septa of dense fibrous tissue, or, as in my case, by completely ossified spicula and membranous lamellæ.

The contents of the cysts are fluids or semifluid, the chemical constitution of which has been found to be an albuminous fluid of different colors. A viscid mucus seems to be the most common occurrence. The color depends upon the accidental admixture of decomposed blood, and may be from a clear transparent to a turbid brownish or even reddish hue. Sometimes one of these cysts contains brown mucus, while another in the same tumor may be filled with a transparent clear liquid. The density or viscidity may also vary in cysts of the same tumor. We are accustomed to this peculiarity in multilocular ovarian tumors. I have often drawn six or seven different kinds of fluid from the larger cysts of one ovarian tumor. It is claimed that cholesterin crystals have been found in tumors of the jaw. I have never seen them. Some of these cysts contain air. Bryk's case gave a tympanitic sound on percussion. The cysts in this case were in open communication with the mouth. In some cases (Falkson and Magitat) the cysts intercommunicated. In my case the largest cysts were entirely distinct, and it was impossible to determine a communication between any two. In cases where this intercommunication or a communication with the mouth exists it is undoubtedly a secondary arrangement which has been brought about by purely mechanical agencies accompanying the growth of the cysts and the pressure of their contents, which may eventually cause erosion

Fig. 2.

and rupture. The size of the cysts varies from a cavity not visible to the naked eye to the size of a hen's egg. The walls of the cysts are, as a rule, smooth and lined by a dense fibrous layer of tissue. Bryk speaks of warty excrescences and scar-like figures in his case.

These tumors have frequently been known to follow some kind of inflammation or injury or irritation of decayed teeth. It is very certain that the growth of these tumors causes local inflammation about the gums, and finally even causes the teeth to become so loose that they fall out, or are torn out by the act of chewing. I cannot well imagine how a decayed tooth can cause a perverted action of the enamel organ which we shall directly find to be the cause of these tumors. Suffice it, we know nothing positive about the exciting causes of this rare disease. The most plausible hypothesis is, perhaps, the one which refers the origin of these cystic degenerations to a heterotopic, embryonic germ, a remnant

Fig. 3.

of the enamel organ, and confesses total ignorance in regard to exciting causes.

The disease is most common during youth, or about the time of puberty. My table would place the largest number of cases at about the twentieth year. Cases have been known to occur as late as the seventy-fifth year (Coote).

Wilks describes a congenital case. This is not surprising to me, as I have both seen a child born with twelve teeth, and known a gentleman who developed a new tooth at the age of sixty-seven.

The history of my case, given above, sufficiently indicates the clinical aspects of these tumors. They become very troublesome to their victims by their large size. Some cases have, however, been known where they were borne as long as twenty-five, and even twenty-nine years. By interfering with the functions of the organs in the mouth, they become dangerous as well as disagreeable, and are among the least beautifying of known tumors, since they cannot easily be hidden or made less hideous by cosmetic aids. They usually cause no swelling of the adjacent lymphatic glands and, in fact, are very slow to infect neighboring organs. Formerly the general impression prevailed that all multilocular cystic tumors were benign. Like most other tumors, advanced age, constitutional weakness, or infirmity no doubt increase the tendency to malignancy; during the early adult stage it is very small. Mr. Syme saw recurrence twice after partial removal. Mr. Eve quotes a case of Jonathan Hutchison's where the autopsy clearly showed secondary deposits in the lymphatic glands, and Mr. Heath saw a recurrence and removed it twelve years after he had completely removed the affected portion of the jaw. Both the latter specimens are in the Museum of the Royal College of Surgeons, Lincoln's Inn Fields, London. We have the authority of Mr. Eve for the state-

ment that the microscopical characters in both the tumors were those of multilocular cystic degeneration.

So far as known to me, the case which gave me cause for this study is the only one that has been observed in a negro. This race is noted for its fine teeth, so long as it remains pure. Dentists claim, however, that mulattoes are very much afflicted by decaying teeth. These circumstances may become of more value in the future when the etiology of tumors of the jaw can be judged on the basis of a more extensive material.

In October, 1884, the young negro was received at the Surgical and Ophthalmic Hospital, and in the presence of the graduating class of the College of Physicians and Surgeons, assisted by Drs. Louis Bauer, H. Wiehmann, Charles Bark, H. Harnisch, E. M. Powers, George J. Bernays, H. Summa, and others, I proceeded to remove the entire tumor. The patient was chloroformed while sitting upright in an operating-chair. The first incision was made in the median line, severing the lips and all the soft parts down to the hyoid bone. I now dissected back all the soft parts along the jaw up to the angle on both sides, and also freed the tumor, in its whole extent, on its lower surface. The most tedious part of the operation, namely, the sawing through of the healthy jawbone above the angles, was now performed. The bone was found to be of unusual hardness, and although two of the best Langenbeck's straight saws, which had been refiled and set, were used, this step of the operation consumed twenty minutes. I now secured the tongue by means of a loop of thread and forceps and quickly trimmed it away from the upper surface of the tumor. The hemorrhage during the operation was considerable. The mental, the submental, the inferior dentals, and the fascial artery of the left side were cut. The inferior dental arteries could not be tied, because they immediately retracted into their bony canals. I found it expedient to push a piece of a match, which was sharpened, into the canal of the right side, the place of section not being more than one-fourth of an inch from the lingula. The artery in the left ramus stopped bleeding after the finger had been pressed over the foramen a few seconds. The wound in the mouth was now closed by transversely stitching the

Fig. 4.

remnants of mucous membrane together under the tongue as well as was possible with twelve sutures. I was tempted to remove a portion of the bagging loose skin, but concluded merely to unite the cut edges and depend on contraction to reduce the immense pouch. As may be seen by Figs. 2 and 3, this expectation was fully realized. The union of the lip took place by first intention; the sutures of the mucous membrane had to be partially removed on the second day on account of a very severe secondary hemorrhage which came from the left inferior dental artery. It became necessary to cauterize the cut surface of the jaw with concentrated perchloride of iron in order to stop the hemorrhage. After this the healing process went on regularly; the patient left for his home in the fourth week. A very hard and unyielding scar now forms the base of the mouth and gives a good support to the tongue. The scar forms a sort of diaphragm extending across from one stump of the jaw to the other.

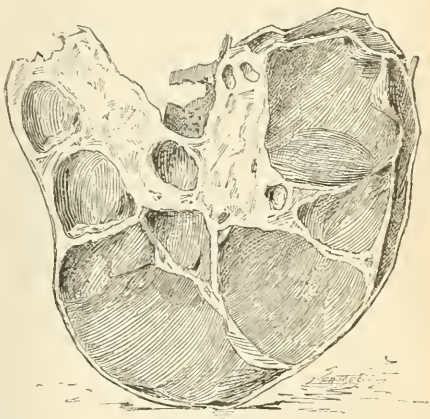

Fig. 5.

By contraction the ends of the rami have been somewhat approximated to one another. Fig. 2 represents the patient after a definite union of all the wounds had taken place.

In order to give the patient a better appearance, and also to prevent further contraction, I consulted Dr. F. W. Hermann, a dentist of this city, who has given considerable attention to prothesis and the special adaptation of artificial teeth in cases of defects of the jaws. He determined to try the very difficult task of making an artificial lower jaw of vulcanized rubber to fill out the defect between the stumps of the rami. The articulation was effected by means of springs attached to the last molars of the upper jaw. Fig. 3 shows the patient as he appears now, nearly six months after the operation, with the artificial plate in position. The cosmetic effect is certainly marvellous. I believe that, with practice and perseverance, the utility may also be much increased. Without the artificial jaw and teeth the patient will be compelled to use his fingers as opponents to the incisors of the upper jaw, in order to properly comminute or masticate solid food. His speech is but little inconvenienced by the loss of his jaw. The patient expresses himself well satisfied with his present condition. The illustrations were all made by the new photo-zincotype process after photographs.

Histo-pathology.—Up to the time of Magitat's investigations all tumors of the jaws were called cystoma, without regard to their microscopical structure, or they were denominated cysto-sarcoma, or cysto-fibroma, according to the opinion of the respective operators in regard to the malignancy or innocence of their cases. If thought to be very malignant, they were called cysto-sarcoma; if benign, cysto-fibroma seemed to fit the case.

Christopher Heath, in his fundamental work on the "Injuries and Diseases of the Jaw," is the first who expresses the opinion that many of these cysts or cystoids of the lower jaw, although apparently in no connection with the teeth, very probably originate somehow through the irritation of diseased or developing teeth.

Magitat, "On the Cysts of the Jaws," defines these tumors as follows: "A cyst of the jaw is a tumor well

bounded and limited on all sides, which has developed within the jaw-bone, and contains a fluid of variable consistency, mingled with solid parts. It always originates from the dental system, and dates back to various stages of development of the tooth-sac." Besides these tumors, which Magitat calls follicular, he distinguishes periosteal cysts. He distinctly says that these cysts do not originate from the enamel epithelium, or enamel organ, as it is usually called.

Falkson's contribution to our "Knowledge of Cysts of the Jaw" is the first investigation which clearly opposes Magitat, and claims the origin of the cysts from the enamel organ. He gives a description and a semi-diagrammatic illustration of the histological details of a tumor which was first macroscopically and surgically described by Caspary.

Professor A. Bryk, of Krakau, describes the minute anatomy of his case, and also gives a semi-accurate illustration of a microscopical section. He entirely corroborates Falkson's claim that the alveolar structure and cysts are an outgrowth of the enamel organ.

Mr. F. S. Eve has accurately examined twelve specimens of cystic tumor, and also corroborates the theory that these degenerations begin from the epithelial cells of the enamel organ, or even goes so far as to claim that they are ingrowths of the epithelium of the gums. Büchtemann also saw an unmistakable connection between the epithelium of the gums and the formation of the tumor.

It would seem, therefore, that the evidence in favor of the theory that these cysts originate from the enamel organ may be summarized as follows: 1, The constant appearance of one layer of narrow columnar epithelium which lines the alveoli; 2, the peculiar network of irregular, star-shaped cells which fill up the alveoli; 3, the absence of blood-vessels in the just-mentioned tissues; 4, the connection of the alveoli, in the form of ingrowths, with the epithelium of the gums.

In order to show more clearly in what respects the alveoli found in the cystic tumors, as just described, correspond to the enamel organ, let me briefly review the development of that structure, as it appears in the embryo. In the second month of embryonic life a dipping down or an ingrowth of the epithelial lining of the gum is noticed along the entire upper margin of the jaws. This is called the enamel germ. This germ now buds out in a number of places, and grows downward into the jaw. Each one of these consists of an outer layer of elongated cylindrical cells, corresponding to the deepest layer of the epithelium of the gum. The centre or interior of the bud consists of more stellate epithelial cells, which have differentiated a peculiar gelatinous intercellular substance. This bud now becomes invaginated, it being pushed forward by the primitive tooth papilla in such a manner that it forms an epithelial cap over the papilla. This cap is called the enamel organ, from which the beautifully regular enamel prisms are formed after the papilla and its cap have become enclosed by the tooth-sac (Kölliker, Waldeyer, Gegenbaur). The very marked similarity between the structure of the tumors and the enamel organ now becomes apparent at a glance. It would appear, then, that the above-quoted authors have established a very strong probability in favor of the hypothesis that these tumors are the result of abnormal growth of the enamel organ. I will now proceed to detail my own observations, and I am glad to be able to advance the above hypothesis to the rank of a positive fact by my observations on the tumor in my possession.

The tumor was of course quite fresh and in the best possible condition for histological examination. For the purpose of cutting and staining fine sections, I was compelled to use decalcinating reagents. By immersion of two small pieces, one from the centre and one from the periphery of the tumor, which had been taken off with a saw, in a two and one-half per cent. solution of muriatic acid, all the calcareous matter was dissolved in twelve hours, and the hardening process was next in order. I used a three-fourths per cent. solution of chromic acid, in which the specimens remained one day. The chromic acid was now reduced, and the hardening finished by placing them in absolute alcohol. The sections were stained in alkaline carmine and picrocarmine; they were then anhydrated and examined in the oil of cloves, which rendered them perfectly transparent.

A section of the fleshy, more porous portion, from near the centre, when viewed with a Hartnack objective No. 4 (equal to about seventy diameters), revealed an alveolar structure, the arrangement being very irregular, at the first glance much resembling an epithelioma. The alveoli were arranged into groups, separated from one another by fibrous layers in which blood-vessels and lamellæ of bone were plainly seen. The alveoli were mostly round, but some of them had processes budding out in various directions. Hartnack No. 7 (magnifying three hundred and fifty diameters) shows the cellular structures, and here, at the first glance, we see that the alveoli, besides being lined with a regular columnar epithelium, are surrounded by a layer of homogeneous pearly substances, which sometimes show slight lines like radii, as if they were projections from between the cylindrical epithelium. This layer was always present, and can be seen in Figs. 6 and 7, surrounding the alveolus, exactly corresponding to its shape, and of about the same thickness as the lining epithelium. This layer is evidently the product of the enamel epithelium, and is certainly enamel substance. The layer of genuine enamel has never been mentioned or recognized by any observer before; it furnishes the keystone in the arch of evidence, establishing the fact that these cysts are the result of pathological development of the enamel organ.

The contents of the alveolus are made up of a peculiar tissue composed of stellate and round cells, with a peculiar gelatinous intercellular substance, which is perhaps the product of degeneration of the cells. It must not be forgotten that these elements within the alveolus are also of epithelial origin. No other kind of tissue could possibly be found in this place, since by their origin the alveoli are as much products of the epidermis as are any of the other organs of the skin, for example the hair or the tallow glands. The whole alveolus, or group of alveoli, are surrounded by a fibrillary connective tissue, with few spindle-shaped cells.

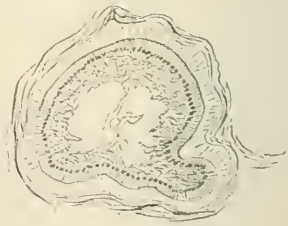

Fig. 6.—Section of an Isolated Alveolus. The centre has become liquefied. (Hartnack, No. 7.)

I may mention here that Mr. Eve, in his Fig. 3, has given a drawing of an alveolus which seems to me to be very similar to my own, and I am inclined to think that his drawing represents either the enamel epithelium with the surrounding enamel, or perhaps osteoblasts with a layer of bone. I cannot agree with his opinion about this most interesting case. It is specimen No. 2234, Royal College of Surgeons' Museum, and accompanied Mr. Christopher Heath's Jacksonian Prize Essay. Mr. Eve further says: "The growth, like all tumor formations, makes no attempt at the higher development of the normal structure," referring to multilocular cystic

disease in general. The tumor of the young negro does seem to make an attempt at a higher development, but certainly never reaches the perfection we find in a developed tooth.

FIG. 7.—Section of the Periphery of an Alveolus, showing the Cylindrical Epithelium, with its Product, the Enamel Prisms. Some indifferent epithelial cells within. (Hartnack, No. 9.)

Among the retrogressive metamorphoses of these tumors, I consider the formation of larger cysts the principal one. The largest cysts in the tumor examined by me had entirely lost their columnar epithelium. Their walls were formed by a dense fibrillary tissue, which appeared like a periosteum, lining the lamellæ of bone that formed the boundaries between the larger cysts. Only rarely was a very attenuated layer of enamel found between the bone and its periosteum, or endosteum, as it were. The process of gelatinous or colloid degeneration of cells has so often been described that I need only mention its presence in my specimen to account for the presence of such liquids in the cysts. I agree with Mr. Eve in the opinion that this peculiar metamorphosis depends probably upon the inherent tendencies of that portion of the gum from which the enamel germs originate. But I believe that these tumors, as a rule, will be found to originate from remnants of embryonic enamel germs, and only rarely, if ever, from epithelial ingrowths occurring later in life.

Falkson draws and mentions the so-called Perl-kugeln that we so often meet with in epitheliomata of the skin and mucous membranes as occurring in the alveoli of these cysts. I can corroborate this fact but cannot compare these formations to the Perl-kugeln of malignant tumors. These cornified plugs of epithelial cells are to be classed among the normal processes always found accompanying the atrophy of the remnants of the enamel organ. Kölliker ("Entwickelungsgeschichte," page 827), says they are found sometimes in connection with the remnants of the enamel germs, while they are often found quite independent between the tooth-sac and the epithelium.

FIG. 8.—Section of Trabeculæ of Developing Bone. Osteoblast cells, gelatinous degeneration of the cells adjoining the osteoblasts.

A section through the periphery of the tumor, near the large cysts, afforded me a very peculiar view. I have illustrated it in Fig. 8. It shows a young portion of cancellated bone-tissue, with the small osteoblast cells of Gegenbaur in the process of development. The interior of the bone is lined with osteoblast cells, but the centre is empty, the fluid which it contained having fallen out of the section. Only some few cells are attached to the osteoblasts, and these are in various stages of decomposition by gelatinous degeneration. This observation would seem to show that perhaps the osteoblast cells play an important part in the development of the cystic tumor. I have long become convinced of the truth of Gegenbaur's proposition, that the formation of true bone is always dependent upon the osteoblast cells. My observations have firmly established that fact in my mind. Seeing now that these cystic tumors are often accompanied by a proliferation of the bone, the question arises, whether or not the abnormal growth of the enamel rudiments is the primary cause of the cystic tumors? It seems plausible that the growth of the bony shell is merely a passive dilatation, but I have propounded the question in this place because it appears to me of importance for a full understanding of these tumors. Since in many cases the bony septa are wanting, and we find only connective tissue separating the cysts from one another, we may safely assume that the formation of these epithelial multilocular cysts of the jaw is dependent upon the abnormal and heterotopic proliferation of the enamel germ or remnants of the enamel organ. Based upon this understanding of these tumors, I may now be permitted to propose the simple but expressive term Enamelogenous Cyst, in the place of the numerous names heretofore used to designate these unique tumors.

THE LAW OF BURIAL.[1]

BY HENRY A. RILEY, ESQ.,

NEW YORK.

THE treatment of the dead and the selection and adornment of the places where the departed are laid to rest are matters of much more interest and concern than many seemingly more important things affecting the living. It is not a matter of surprise, therefore, that the laws of all nations from the very earliest times should have laid especial penalties upon any disrespect shown either the dead body or the tomb.

The history of burial rites, ceremonies, and laws is a most interesting one, and perhaps the best essay on the whole subject is found in the dry pages of a New York law book,[2] where the Hon. Samuel B. Ruggles treats in a most learned way of past laws and present duties in connection with the dead. The two modes of disposal of the dead in general use have been inhumation and burning, and Sir Thomas Browne, in his quaint treatise on urn burial, thus writes concerning them: "Men have been fantastical in the singular contrivances of their corporal dissolution, but the soberest nations have rested on two ways—inhumation and burning. That interment is of the elder date the examples of Abraham and the Patriarchs are sufficient to illustrate; but Christians have abhorred the way of obsequies by fire,

[1] Read before the New York Society of Medical Jurisprudence and State Medicine, March 12, 1885.
[2] 4 Bradford Rep., 502.

and though they stickled not to give their bodies to be burned in their lives, detested that mode after death, affecting rather a depositure than an absumption, and conforming themselves to the will of God, which required them to return again not to ashes, but unto dust. But burning was not fully disused till Christianity was finally established, which gave the final extinction to these sepulchral bonfires."

Sir Thomas Browne certainly stated the custom and the law correctly as regards Christian nations for the time when he wrote, but the chronicler of the present day will be obliged to record a partial return, at least, to the mode of cremation. In England itself, where conservatism is a matter of religious belief in a matter like this, the pendulum of practice has begun to swing to the other extreme, so that one of the principal judges of the realm has in a very elaborate opinion decided that cremation is not illegal; and societies to furnish facilities for cremation are springing up in various parts of Great Britain.

The Bible has frequent reference to the practice of sepulture as distinguished from burning, and it is recorded of the Patriarch Joseph that "when he died he was put into a coffin and embalmed." In an interesting case before the Consistory Court of London, in 1820 (Gilbert *vs.* Buzzard, 2 Hagg. Rep., 334), Sir William Scott says of the place of sepulture: "In ancient times caves seem to have been in high request, then gardens or other private demesnes of proprietors, inclosed spaces out of the walls of towns or by the sides of roads, and finally in Christian countries churches and churchyards, where the deceased could receive the pious and charitable wishes of the faithful who resorted thither on the various calls of public worship. In our own country the practice of burying in churches is said to be anterior to that of burying in what are now called churchyards, but this was reserved for persons of pre-eminent sanctity of life." The use of coffins or some similar receptacle for the dead has been almost universal in cases of sepulture, though the material used for such coffins has varied greatly. They have been made at different times of wood, stone, metals, marble, and even glass.

In 1786 the Grand Duke of Tuscany attempted to forbid the use of coffins, on the ground that the dissolution of bodies would be hastened and the health of the living better secured by depositing the bodies in the ground without any covering. The means adopted to carry this radical measure into effect were calculated to offend every sentiment of religion and humanity. It was ordered that the bodies of all dead persons, of both sexes and of every age and condition in life, whether dying of old age, at the very beginning of life, of loathsome diseases, or by accident, should all be brought out naked from the houses, tumbled into a night-cart at the sound of a bell, and conveyed to a pit without the city walls, there to decay in one undistinguishable mass. It is not surprising to learn that an edict of this kind utterly failed of its object, and was revoked not long after its promulgation.

The English law has been held to secure to a person what is called the right of burial; but there is no absolute right that a person should take with him to his last dwelling-place a coffin or large burial-chest. This was the very point decided in the case of Gilbert *vs.* Buzzard, just mentioned, where the relatives of the deceased insisted on burying him in an iron coffin, which the cemetery authorities refused, on grounds of health, to admit. Upon this issue the Court held that the only inherent right of a British subject, was that of burial of the body. Still, in this case, it was decided to admit the iron coffin, if a proper compensation was made for its supposed indestructibility. As the cemetery was established for the use of future generations as well as the living, it was not held right to admit iron coffins in such manner as to speedily fill it up without large compensation for the privilege.

Without discussing further the interesting question of the history of burial, the present law relating to the dead may be considered under three heads:

I. After death, and before burial.
II. At burial.
III. After burial.

The disposal of the bodies of the dead by cremation, or fire-burial, as it is generally termed in England, as has been stated, is becoming so common, by the rapid erection of furnaces where the dead really turn to ashes, that there may be in the future some slight changes in the application of existing laws.

The legal principles involved can hardly be varied, however, for they are inherent in the change from life to death and do not affect the methods used.

The adoption of cremation has been so recent and has had as yet so trifling an influence upon burial customs and laws, that but little attention need be given to any possible effect wrought by this new method.

In this country there has been no instance as yet where the propriety and legality of cremation has been called in question. It is not probable, however, that under the free spirit of our legal regulations, there will ever be a judicial decision interfering with perfect freedom of choice in regard to the mode of disposal of the dead. The paramount interest of the public health may at certain times prescribe some uniform mode for contagious diseases, but aside from this no interference is at all likely.

I. In considering the first point, viz., laws in regard to the body after death and before burial, it will be well to discuss first, ownership and custody of the dead, and secondly, the duty of burial

1. Ownership and custody of the dead. There is no such thing as ownership of the dead, in the sense that the term is applied to ordinary articles of barter and sale. The corpse cannot be sold by the surviving relatives for a price, though it would seem that the deceased could himself, by will or other written instrument, give such a right to the body after death that the donee, having once acquired possession of it, could hold it as against the relatives. If, however, the relatives have possession, and desire to bury it in a family plot, it is doubtful if any court of equity would enforce the delivery to a person claiming it under the will. Such an instance would be that of a person selling his body to a physician for purposes of dissection and the relatives refusing to recognize such sale (Am. Law Times, July, 1871). The question is viewed from the standpoint of public policy, health, and decency, and these considerations will be held to override any individual claims to the dead body. In a case reported in 90 Mass. Rep., 281, the rule is stated to be as follows: "A dead body is not the subject of property, and after burial it becomes a part of the ground to which it has been committed, 'Earth to earth, ashes to ashes, dust to dust.'"

Sir William Blackstone, in his Commentaries (2 Bl. Com., 429), says that although an heir has a property in the monuments or escutcheons of his ancestor, yet he has none in his body or ashes.

The same principle is stated in Secor's case (31 Leg. Intel., 268), and Guthrie *vs.* Weaver (1 Mo. App., 136). Sir Edward Coke (3 Inst., 110) writes thus in 1613, when the question was a novel one: "At the assizes in Leicester in Lent, *anno* 10 Jac., the case was thus: One William Hain had in the night digged up the graves of divers severall men and of one woman, and took the winding sheets from the bodies and buried the bodies again, and I advising hereupon for the rareness of the case, consulted with the judges at Sergeant's Inne on Fleet Street, where we all resolved that the property of the sheets was in the executors, administrators, or other owner of them, for the dead body is not capable of any property, and the property of the sheets must be in somebody; and according to this resolution he was indicted of felony in the next assizes, but the jury found it but petit larceny, for which he was whipped, as he well deserved."

A Missouri court (Guthrie *vs.* Weaver, 1 Mo. App., 136) has gone even farther than this, and maintains that there is no ownership even in the coffin and shroud. It says: "When a human body has been interred with the knowledge and consent of those who, up to that moment, may have owned the coffin and shroud, these articles are irrevocably consigned to the earth, and all property in the purchasers of them is at an end. In a later case, however (State *vs.* Doepke, 68 Mo., 208, 1878), this case seems to have been practically set aside as to this point.

There is in the law books but one case which takes the opposite view as to ownership, and in that (Bogert *vs.* City of Indianapolis, 13 Ind., 138) the Court states broadly: "The bodies of the dead belong to the surviving relatives in the order of inheritance as property, and they have the right to dispose of them as such within restrictions analogous to those by which the disposition of other property may be regulated." This decision has been much criticised, and is certainly not the law outside of Indiana.

In the case of dead bodies found on the seashore and cast up from a wreck, there is no ownership allowed to the finder, either in the bodies themselves or the articles upon them. In a Massachusetts case (13 Pick., 402) the removal of articles of dress by the finder was adjudged to be a felony.

It is true, nevertheless, that the courts recognize a sort of *quasi*-ownership on the part of near relatives as against those of more remote kinship, such as to enable them to keep, protect, and bury the body decently, should a claim be made for possession of it. The time usually elapsing between death and burial is so short that the question of *quasi*-ownership is not often brought before the courts until an interment has taken place, and then the question is complicated by this very fact, for public policy demands that a body shall not be disturbed except for the best of reasons. In regard to the rightful custodian of the dead, it is said in Secor's case (31 Legal Intelligencer, 268) by Judge Pratt: "The executor is the person having the lawful possession of the remains," and in Sears *vs.* Gidday, a recent Michigan case (2 Northwestern Rep., N. S., 367) it was held that the husband was liable for the funeral expenses of his deceased wife, although she left all her property to another person, and the latter individual assisted in the arrangements for the funeral. The liability for the expenses would naturally admit of the inference that whatever right of ownership existed was in the husband.

In an article in the *Albany Law Journal* (10 Alb. L. J., 70) on the subject "The Legal Custodian of Deceased Bodies, Who is?" the following deductions are made: 1. That the right to protect and bury a corpse is in the executor. 2. In the absence of any testamentary disposition it devolves upon the widow, husband, or next of kin. 3. The owner of the land has the right of action in trespass to protect a grave or sepulchre from detriment. 4. That a corpse is in no way subject to sacerdotal power or ecclesiastical cognizance. 5. That the right to protect a corpse implies the right to select the place of its sepulture. 6. That during her lifetime the widow of a deceased husband has the direction and control of the place of interment, and so the husband over his wife's remains.

2. In regard to the duty of burial. This obligation follows partly from the idea of *quasi*-ownership existing in the executor, and partly from considerations of public health and decency, which demand that this last sad office shall be speedily performed. In Rex *vs.* Stewart (12 Ad. and Ell., 773) an old case, it was held that the duty of providing for the corpse and carrying it to the grave decently covered is thrown upon the person under whose roof the death takes place; for such person can not keep the body unburied nor do anything which prevents Christian burial: he cannot, therefore, cast it out, so as to expose the body to violation, or to offend the feelings or endanger the health of the living. In 2 Williams on Executors, p. 829, it is said that the executor must bury the deceased. In Ambrose *vs.* Kenison (10 C. B., 776) it is held that the husband is bound to bury his deceased wife, and the wife to bury the husband.

In recent times it is also held to be a matter of duty devolving upon the public authorities, and an interment will always be provided at the public expense where there is an inability to bury the dead on the part of surviving relatives, or an absolute refusal to do so for any reason.

II. In discussing the second division of the subject, viz., at burial, the questions of the choice of a burial-place and the right to exclude persons from a funeral may be considered.

First, the choice of a burial-place. In regard to this, it may be said that the legal complications resulting from the exercise of the choice, do not usually arise before interment, but far more frequently afterward when the question of removal comes up.

It is generally conceded that a testator has a right to select in his will a place of burial, and that this wish must prevail over that of his family in case it is known before interment (Brick Church Case, 4 Brad., 503). In a recent unreported New York case this acknowledged right of the testator was held to have lost its force when the body had been buried for some years before a will was found which expressly directed that it be buried in another cemetery. The Court refused under the circumstances to order a removal.

In Durell *vs.* Hayward (9 Gray, 248) Judge Bigelow said: "The indisputable and paramount right as well as duty of a husband to dispose of the body of his wife by a decent sepulture in a suitable place carries with it the right of placing over the spot of burial a proper monument or memorial."

In the absence of any testamentary selection, the cases seem to hold that the wishes of the husband or wife shall have preference over those of the next of kin. This is, however, an inference drawn mainly from the cases on removal of the dead (see Wynkoop *vs.* Wynkoop, 42 Penn. St., 293).

In regard to the second point, of the right to exclude persons from the funeral, it may be said that it is a matter of surprise to have such a right claimed, because all animosities between the living should be quieted in the presence of the dead. When the funeral services are held in a church this question will probably never arise; there was, however, not long since, in Rhode Island, a case where the person who had custody of the deceased and charge of the funeral services held them in his own house and forebade a certain other person to attend. The latter was forcibly excluded from the house and afterward brought suit for damages, on the ground that the service was one which the public had a right to attend. The Court decided, however, that the occasion was not so public as to carry with it this right, and that the ownership of the house gave the legal right to the owner to forbid the attendance of persons objectionable to him.

III. The third division is the body after burial. This is practically the question of removal, as the body, when once decently interred, is not likely to be the subject of litigation or interference except as the attempt to remove it is made.

The dead body may be removed by the cemetery authorities, by the health officials, or by the relatives, when proper cause is shown. The statutes of most of the States permit cemetery authorities to remove bodies once interred to other locations when some paramount public interest is involved.

The march of business may possibly render a neighborhood so valuable as to cause a graveyard to be closed and the bodies removed. This is not often done, because public sentiment would naturally feel aggrieved and oppose the removal, but the law, under careful restrictions

as to notice, permits such removal if the application be approved by the courts.

The supreme interest of the public health will also allow the removal of bodies when their continuance is prejudicial to the health of the living. This is paramount to all considerations of affection or sentiment.

It is, however, when the attempt to remove the dead body is made by relatives that the great body of litigation on the subject has grown up.

The law of burial, as regards the place selected and the right of permanent resting-place, was very fully discussed in 1856 by Hon. Samuel B. Ruggles, Referee (4 Brad. Rep., 503), in an application for the widening of Beekman Street, New York City, which case has been already cited. The widening of Beekman Street made it necessary to cut through certain vaults previously used for burial, and required the disinterment and reinterment of the bodies in some other place.

The body of Moses Sherwood was in one of these vaults, and his daughter, Mrs. Maria Smith, insisted that the body should be reinterred in a grave by itself, and the cost of removal defrayed out of funds in court. The Referee reported in favor of this claim, and the Supreme Court confirmed the report. The conclusions of Mr. Ruggles' elaborate argument were to the effect that the right to bury a corpse and to preserve its remains in the absence of testamentary disposition belonged to the next of kin exclusively; that the right to protect the remains included the right to preserve them by separate burial, to select the place of sepulture, and to change it at pleasure (1 Am. Law Rev., N. S., 62). This latter point has been somewhat restricted by more recent decisions, and Mr. Ruggles explains that the statement that the right to bury the corpse belonged to the "next of kin" was not intended to exclude the right of the husband in the case of the wife, or *vice versa*.

The cases where removal is attempted by relatives range themselves under the following heads:

1. The husband or wife has not an absolute right to remove the body against the will of the next of kin.

2. The next of kin cannot remove the body against the will of the husband or wife.

3. The next of kin cannot remove the body against the will of other next of kin of equal relationship, and public institutions have no rights as against the next of kin.

4. The owner of the lot has no such absolute right to the realty as to carry with it the ownership of the bodies buried in the lot. These are held in trust.

These points prove by the mere statement that an interment is not a slight matter, to be changed by sudden whim or impulse.

The law favors "the repose of the dead," and while reinterments are frequently made, it is generally in those cases where every one interested is agreed that such a course is the proper one.

1. In Wynkoop *vs.* Wynkoop (42 Penn St., 293), tried in 1862, it appeared that Colonel Francis Wynkoop had been buried in his mother's plot in Mount Laurel Cemetery. A few months later the widow applied to the Court, in the capacity of widow and also as administratrix of the estate, for an injunction restraining her husband's mother, sister, and brother from interfering with her plan of removing the body to another cemetery. The Court refused the application, saying: "The bill asserts a fixed legal right in the plaintiff in two capacities, (1) as administratrix and (2) as widow. As to the first, the absolute duty to bury terminated at the burial; second, as widow in this case she would appear to have no rights after the interment. Suppose a woman has had three husbands, who have all died leaving her a widow (3 Rawle, 304), is she to be burdened with the duty and vested with the charge of their three bodies against the express wishes of blood-relations and next of kin of each?"

The Court further said that "the fact that the body is deposited in the burial-place of his mother, in consecrated ground, and that he was buried with the ceremonies of the church and the honors of war, is sufficient to justify us in refusing permission to a removal under the circumstances."

A more recent case, Weld *vs.* Walker, tried in Massachusetts in 1879, is more favorable to the claim of the husband to remove the body of his wife, but still places some restrictions upon its exercise. In that case Mary P. Weld, wife of the plaintiff, died at Boston, in 1875, and was buried in Forest Hills Cemetery, in a lot belonging to the husbands of her two sisters. Mr. Weld owned a lot at the time in Mount Hope Cemetery, but allowed the interment to be made in the other cemetery. He afterward wished to remove the body to Mount Hope Cemetery, and alleged that in the resting-place where it was, he had no right to enter the plot to erect a monument or adorn the grave. In rendering the decision permitting the removal, Judge Morton said: "I think that the right to select the place of burial of the wife involves the right in the husband to change it, if from a change of circumstance or other good reason he desires to do so. The fact that the husband consented to the original burial is not conclusive against his right to make a change. It may be that the right of the husband is not an absolute right. If he should act in wanton disregard of the rights of the other relatives or of the feelings of the community, perhaps a court of equity would not aid him. But his rights will be protected by a court of equity when he acts properly. In the case at bar, the plaintiff gave a reluctant consent to the burial of his wife in the lot in Forest Hills Cemetery. This was not, however, expected to be her final resting-place, as the parties contemplated that, at the death of the husband, her remains were to be removed and laid beside his."

2. The next of kin have no absolute right of removal against the wishes of the husband or wife. In Secor's Case (31 Leg. Intel., 268), it appeared that the widow had buried the remains of her husband, when shortly afterward the son, who said that he had purchased another burial-place in accordance with the directions of his father, attempted to remove the body. The Court granted a perpetual injunction against any attempt of the kind, saying: "A proper respect for the dead, a regard for the tender sensibilities of the living, and the due preservation of public health, require that a corpse should not be disinterred or transported from place to place except under extreme circumstances of exigency."

3. The next of kin have no fixed rights as against each other, and public institutions have no rights at all against the next of kin. The case of Lowry *vs.* Plitt (11 Am. Law Review, 781) is a Pennsylvania case tried in 1877. Mrs. Lowry, at the time of her death (1866), had no burial-place and her children also had none; she was therefore buried in the lot belonging to her sister, Mrs. Plitt. Three years later one of her sons died, leaving $5,000 for his executors for the purpose of erecting a family tomb, where should be placed his own body, that of his mother, and other members of the family, if they desired. The executors with another of the sons applied to the court for permission to remove the body from Mrs. Plitt's lot. One of the sons joined Mrs. Plitt in opposing the removal and the Court refused to permit it, saying: "The law favors the repose of the dead. When they are inurned in the places selected by them, it must be something more than sentiment or abstract right which will induce us to enforce the claim of the next of kin by the invasion of the burial-place of another. In such case it may well be questioned whether a right of the next of kin exists at all."

It occasionally happens that the prominent position of the deceased, especially in political matters, makes the question of removal a public one. An illustration of this is found in the desire of Congress, expressed many years ago by a resolution, to remove the body of George Washington from Mount Vernon to the Capitol, but the legal

representatives declined to permit it and the matter was dropped. The City of Philadelphia, in the case of Stephen Girard, the celebrated philanthropist, desired to remove his body from Holy Trinity Church, but the court intervened to prevent the desecration (4 Am. Law J., 97).

4. The owner of a burial-lot holds the bodies buried in it under a trust. This was decided in Pierce *vs.* Swan Point Cemetery (10 R. I., 227). Mr. Metcalf, the deceased, was buried in a lot belonging to himself in Swan Point Cemetery. This lot fell by inheritance to his only daughter, Miss Almira F. Pierce. Thirteen years later the widow, Mrs. Metcalf, removed the remains to another plot, and Mrs. Pierce applied to the courts for an order directing their return to the first resting-place. The Court directed this to be done, saying in the opinion: "The person having charge of a dead body cannot be considered as the owner of it in any sense whatever. He holds it only as a sacred trust for the benefit of all who may from family or friendship have an interest in it, and we think that a court of equity may well regulate it as such, and change the custody, if improperly managed. So in the case of the custody of children, certain persons are *prima facie* entitled to their custody, yet the Court will interfere and regulate it." The position of the Court was that the ownership of a burial-lot was a trust to be regulated like other trusts, and did not permit the ordinary exercise of the rights of absolute uncontrolled ownership.

This theory of the trusteeship of the owner of the burial-lot is an advance upon former decisions, and in principle would properly apply not merely to the owner of the lot, but to any one who by kinship, such as husband, wife, father, or child, has a claim to the custodianship.

The last important case on the subject, that of Weld *vs.* Walker (*supra*), goes farther than this one in Rhode Island, and, while recognizing a trusteeship to be regulated by a court of equity, states that the husband has a right to remove the body of his wife, "if from a change of circumstances or other good reasons he desires to do so."

The judge of what constitutes the "change of circumstances or other good reasons" is not the husband himself, but the Court to which the facts are made known. There is no criterion by which a person can determine in advance the right of removal. Each case will have to be judged by itself, with the certainty that the Court will favor the "repose of the dead."

DOES LARYNGEAL STENOSIS CAUSE PULMONARY HYPERÆMIA?

By R. VAN SANTVOORD, M.D.,

NEW YORK.

In The Medical Record of May 30, 1885, Dr. J. E. Winters answers certain critics who have ventured to question his assertion that prolonged croup leads to congestion, splenization, and œdema of the lungs, and he cites an apparently formidable array of authorities in his support. I should like to say a few words in answer to his article.

It is not to be denied that if stenosis of the larynx resulted in a more or less enduring increase of the mean negative pressure within the lungs, the congestive phenomena so well outlined by Dr. Winters would probably be occasioned. Such a mechanism appears to be exemplified in many deaths that occur from rapid suffocation in previously healthy subjects. Tidy (vol. ii., p. 339) states that in death from asphyxia the "lungs in most cases are gorged with blood." Many cases of suffocation may be cited in demonstration, such as that of a man suffocated by inhaling a piece of potato-skin into the larynx, in whom congestion of the lungs and right cavities of the heart was found,[1] or the case of a workman smothered in sand, in whom intense uniform congestion of the lungs was found.[1]

M. Tardieu, in commenting on a case under discussion,[2] speaks of the finding of a quantity of foam containing very fine bubbles as precisely the state of affairs almost constant in strangulation and suffocation. In cases of death in which occlusion of the air-passages might be supposed to have been the principal factor, the absence of congestion or œdema of the lungs may often be plausibly explained by supposing that the blood-vessels of the lungs have expelled, by post-mortem retraction, the excess of blood that existed in them during the active struggle for air, or death, though apparently due to obstruction of the air-passages, may in reality be caused by some other factor, as shock, etc. Dr. Loeven [3] found that when a ligature was suddenly tied around the trachea of a rabbit so as to *totally* occlude it, death resulted after only two or three convulsive inspirations. After section of the pneumogastrics the same procedure caused death from gradual asphyxia in about a minute. The possible factors that may cause death in apparent asphyxia are discussed in works on medical jurisprudence, etc.

It is conceivable that death might occur in diphtheritic croup from the sudden occlusion of the larynx by a detached piece of membrane, or from the sudden stoppage of a tracheotomy tube, and in these cases congestion of the lungs might indeed be produced as in the above-cited instances. As a rule, however, we have to do with a *stenosis* causing dyspnœa, which lasts for hours and perhaps days, with exacerbations and remissions produced by temporary lodgment of secretions in the narrowed air-tube, etc. It is my belief that under these conditions the violent inspiratory efforts of the patients draw in more air past the obstruction than is forced out again, the result being that the mean pressure in the interior of the alveoli and bronchi is greater than normal, and that this increased intra-alveolar pressure more than overcomes the tendency to pulmonary congestion, which otherwise would exist. This belief is founded on the facts that in persons suffering from laryngeal or tracheal obstruction the chest is observed to be greatly distended, and in the examination of the lungs removed post mortem from patients who have died with narrowed air-passages an amount of emphysema is seen, which to me appears more extensive than could have been caused secondarily to other lesions. I have made fourteen autopsies on children who have died in the Randall Island Infants' Hospital from diphtheria with laryngeal stenosis, tracheotomy not having been performed in most of them. In all extensive bronchitis existed. In all but one catarrhal pneumonia is recorded as having been found. It is possible that among the earlier of these I recorded some cases of atelectasis with congestion as pneumonia.

These cases were, for the most part, in foundlings, in whom uncomplicated bronchitis is very common, or in diphtheria following measles or scarlet fever. The percentage of pneumonia is, then, far larger than might be expected in the ordinary run of cases, judging from the records of other observers. In one case only was there any pulmonary congestion that was not accounted for by pulmonary collapse or pneumonia. The latter did not differ, in character or distribution, from similar lesions found in cases of bronchitis in which no laryngeal lesions exist. The emphysema, in cases which I have seen since, being especially interested in the subject, seemed more extensive than would be expected as a secondary effect of the inflammatory lesions, although it must be confessed that uncomplicated bronchitis in children is often attended by a good deal of emphysema. It seems probable, however, that the distention of the lungs found post mortem does not fully represent their distended condition during the active struggle for breath before death.

[2] Annal. d'Hyg., 1855, p. 139.
[3] Les diverse formes d'Asphyxie, Gaz. des Hôp., xlv., pp. 68–74, 1872

My own experience confirms the description given by Oertel, to whom Dr. Winters appeals, unless when Oertel writes of hyperæmia of the lower lobes, etc., he means a hyperæmia distinct from that which always accompanies atelectasis and broncho-pneumonia. The high position of the diaphragm spoken of by him would result from the atelectasis. Oertel says nothing about the mode of production of these lesions, beyond what may be inferred from his statement that the consolidation found in such lungs is identical with what is usually called "catarrhal pneumonia." As in my fourteen cases I found only one of diffuse hyperæmia and one of diffuse œdema, I believe that these conditions, being exceptional, must have been due to something else than the laryngeal stenosis.

I shall not attempt to follow Dr. Winters in his copious citation of authorities. I prefer to appeal to the results which have been found to follow artificial obstruction of the air-passages in previously healthy animals, as these results show the effect of uncomplicated stenosis, and afford a solid basis of fact which is far more satisfactory than an attempt to interpret directly complex phenomena which have to do with so intricate a subject as the physiology of respiration and its effects under different circumstances on the pulmonary circulation.

Köhler[1] produced tracheal stenosis in healthy animals by twisting lead-wire about the trachea so tightly that marked dyspnœa was caused. The immediate effect of the ligation was marked diminution of the number of respirations per minute. In every case respiration was so increased in depth that more air was inspired and expired at each respiratory act than in normal respiration. In rabbits the total amount breathed in a minute was less than normal. In dogs and cats, however, a given volume of air was inhaled and exhaled in about one-half the time in which it would have been done normally. Up to a certain point the frequency of respiration diminished, the amplitude of respiration and total amount of air breathed increased with the increase of the obstruction.

After from three to five weeks, respiration would again approach its normal frequency, and the animals would die from the following secondary changes in the heart and lungs: First, a high degree of dilatation of both heart-cavities; second, a very intense hyperæmia of the lungs, such as is otherwise seen only as the result of lesions of the cardiac valves, with unaltered parenchyma; third, extensive vesicular and intralobular emphysema; fourth, the finest bronchi were filled with catarrhal secretion.

In the production of this emphysema Köhler mentions two factors: First, paralysis of bronchial muscular fibres, which takes place gradually as the result of over-exertion incident to very deep inspiration; second, the limited outflow and stagnation of the bronchial secretions caused by the tracheal ligature.

Bernard[2] states that "it is certain that in violent inspiratory efforts the pulmonary tissue may break and tear," and that he has seen the lungs become emphysematous, in previously normal animals, after breathing irrespirable gases. He states also that the same effect is produced by the slow and labored breathing following section of the pneumogastrics. More or less extensive rupture of alveoli is seen in many cases of rapid asphyxia, as in death from strangulation (Tidy, vol. ii., p. 429). This tearing takes place more readily in the tender tissues of young animals than in the old (Bernard). It is therefore an established fact that pulmonary emphysemas found after death from stenosis of the upper air-passages may occur entirely independent of previous collapse or other lesion.

Köhler found also extensive hyperæmia of the lungs, a hyperæmia such as is commonly seen only as the result of lesions of the cardiac valves. He states that this hyperæmia was due to the secondary giving out of the heart and vaso motor centre. The right side of the heart is strained by the large amount of blood aspirated into it by the distention of the thorax, by the increased positive intra-pulmonary pressure caused by deep inspiration, by which the passage of the blood through the lungs is rendered difficult, and by the "vesicular and intralobular emphysema which develops inevitably after long-continued mechanical obstruction to respiration." This emphysema, he states, "gives rise to marked contraction of the capillaries of the affected parts, and from this results again obstruction to circulation (checking the flow of blood in the central vessels), accumulation of carbonic acid from lessened exchange of gases, and so to deficiency of oxygen."

The special strain on the left heart comes mainly from the increased blood-pressure in the peripheral vessels, which has been shown to exist (Köhler) in animals with stenosed trachiæ. The contraction of the peripheral vessels giving rise to it, results from irritation of the vagi and the constant muscular effort of labored breathing. This last factor, of course, makes large demands on the heart as a whole.

In one of my own cases, above referred to, diffuse hyperæmia of the lungs existed, in another œdema. In these two, cardiac changes secondary to the stenosis may have occurred. In the others, the absence of any hyperæmia "resembling that seen otherwise only as the result of valvular lesions of the heart," would seem to indicate that death resulted from causes other than heart-failure secondary to laryngeal stenosis.

Finally, Köhler found that the smaller bronchi were filled with catarrhal secretions. This condition recalls Niemeyer's statement that bronchial catarrh is a necessary consequence of laryngeal stenosis, because the rarefaction of the air in the lungs caused by the obstruction to entrance of air during deep inspiration must cause hyperæmia, just as would a cup applied to the skin.

Dr. Winters alludes to this explanation, and to the criticism on it by Steiner, in his article on croup in Ziemssen's "Encyclopedia," with great emphasis. Steiner's comment is, "Niemeyer seems to me in this explanation of catarrh in croup, which indeed is not to be disputed, to lay too little stress on the condition of inflammation of the air-passages, and too much on the mechanical factor." The considerations given above, together with the fact that in long-standing tracheal stenosis dilatation of bronchi below the stenosed point exists,[1] seem to indicate that this mechanical factor, in laryngeal *stenosis*, has no existence. Köhler incidentally states in his above-quoted article, that rabbits, which can live for weeks in a state of marked dyspnœa from a ligature about the trachea, die in from twelve to thirty-six hours from catarrhal pneumonia if the mucous membrane of the air-passages is exposed. Certainly, with them direct irritation causing inflammation vastly outweighs the mechanical factor, if indeed the latter exists at all. Köhler's statement that the accumulation of mucus in the air-passages of the animals experimented on is due to the stenosis of the trachea, seems most probable, especially as no catarrhal pneumonia resulted. In the human subjects under discussion the bronchitis results, I believe, from the extension of the inflammation downward, as a rule. The obstruction of the air-passages, by preventing the egress of inflammatory products, may indirectly favor the development of collapse and broncho-pneumonia; and early performance of tracheotomy may, *after inflammatory changes have developed below the point of obstruction*, do something toward limiting their extent. The above-mentioned fate of the rabbits in whom the air-passages were opened recalls dangers resulting from operation upon which little stress has been laid in the present discussion.

To recapitulate, I believe that it has been proved:

[1] H. Köhler: Archiv für exper. Pathol. u. Pharmakol., vii. p. 1, 1877.
[2] Leçons sur les Anesthésiques et sur l'Asphyxie, p. 347. Paris, 1885.

[1] Riegel: Ziemssen's Handbuch, B. v., Hft. 2, p. 234.

1. That total or almost total occlusion of the air-passages may give rise directly to pulmonary hyperæmia. 2. That tracheal or laryngeal *stenosis* does not give rise directly to pulmonary hyperæmia, but, on the contrary, to over-distention, emphysema, and anæmia of the lungs; *secondarily*, heart-failure and consequent congestion of the lungs may occur. 3. The pneumonia found complicating laryngeal croup is catarrhal pneumonia developing from the extension of the inflammation downward, just as would happen if no stenosis existed. The only effect the latter has upon its development is indirect, in that stenosis of larynx or trachea prevents the free egress of bronchial secretions.

There are good reasons for the early performance of tracheotomy, but the danger of pulmonary congestion, "splenization, and œdema" occurring as a direct result of laryngeal obstruction, is not, in my opinion, one of them.

DIAGNOSIS OF CATARACT WITHOUT THE AID OF AN OPHTHALMOSCOPE.

By C. A. BUCKLIN, M.D.,

NEW YORK.

The first class of cases having cataract who call on their physician for advice are those who have exhausted the resources of the optician in trying to obtain glasses, without success. Before taking the necessary steps to establish the diagnosis of incipient cataract, the observer should exclude a few common causes of imperfect vision, for the simple reason that should he examine for cataract and fail to find it, he would be prevented for several days from excluding several other common causes of defective vision.

Irregular forms of refraction, which the optician would probably overlook, are excluded by directing the attention to a large clock-dial at ten feet; if some two opposing figures are decidedly darker than any other figures on the dial, there is an irregular refractive error which requires correction. If the figures all appear *equally* dark, this irregular form of refraction can be excluded with reasonable certainty.

Should the pupils be very large, one would be suspicious of glaucoma; while if, on the other hand, they are small, this disease is excluded with reasonable certainty, provided neither eserine nor atropine has been used. You may next proceed to the demonstration of the existence of incipient cataract.

Drop one or more drops of a solution of atropine, containing one grain to two fluidrachms of water, in the eye. If the pupil dilates full and round, another common form of disease which is frequently mistaken by the inexperienced observer for cataract is excluded, namely, attachments of the iris to the lens with exudation into the pupil.

The pupil being fully dilated, the room is darkened as well as possible. To examine the left eye, place a lamp to the left hand and a little in front of the patient; it should be at about the same height as his eye. You should carefully focus the light on the dark, large pupil with a magnifying glass (Nos. 2, 3, or 4 will answer best). The light should be so thrown upon the pupil that a line passing through the centre of the lens would form an angle of forty-five degrees with the line representing the optical axis of the eyeball. If there are any opacities in the lens, you will see them as small punctate spots.

To examine the right eye, the position of the lamp or patient is so changed that the light may be focused upon the pupil at a corresponding angle. Light thrown by a concave mirror into the eye will show these spots as black specks on a red ground.

The second class of cataract cases who consult their physician are those who have a white spot in the pupil, which is so easily seen that the most careless observer cannot fail to see it.

The questions which immediately arise are: Is it complicated? Is it ripe? Can it be cured?

At the present day it is only necessary for the successful removal of cataract that the patient, with back to the window, can no longer count fingers at a greater distance than two feet, and can distinguish the light from a candle in a dark room at fifteen feet, equally well when held above, below, to the right, and to the left of the eye. I consider these requirements the minimum which is necessary to make one confidently expect satisfactory results. If they can count fingers at a greater distance than two feet it is very questionable if the cataract is ripe enough to warrant one who makes any pretence of being conservative, in operating. I have operated with good results, and without any reaction following the operation, where the person could count fingers promptly at three feet. You are very apt, however, in these cases, to leave too much of the cataract in the eye.

There are occasional cases where the changes are principally in the cortex of the lens and its nucleus is perfectly clear. Such persons may count fingers at a great distance, and still be ready for operation. On the other hand, the change in the lens may be chiefly in the nucleus, and only slight changes in the cortex, in which case, although the fingers were counted badly, the cortex would stick to the capsule when the lens was extracted. The physician can only depend upon the distance at which fingers can be counted when the back of the patient is turned to the light of the window for his measure of the degree of development the cataract has attained. The less the distance at which the fingers can be counted, and the greater the distance at which the light can be seen, the greater are the chances for a favorable result.

When one considers that some respected authorities state that if fingers can be counted, "it precludes the idea of an operation in ordinary cases of cataract," it will be at once seen that what I state as being the minimum requirements are much more liberal. I ask for no riper cataract than one through which fingers can be counted at twelve inches only. I do not hesitate when they can still count fingers at two feet, and have repeatedly operated where fingers could be counted at three feet. No experienced specialist would ever allow any process of artificial ripening to be practised on his own eye.

The statements I make regarding the necessary requirements to make the prognosis in cataract operations favorable are based upon my own personal experience, and have not been influenced by the data or dogmas of other operators. I would never think of operating on an unripe cataract without making the peripheral cut in the capsule. I consider all other methods of opening the capsule objectionable where fingers can be counted.

The time having arrived when a cataract can be removed, all delay beyond this period only increases the chances of accident. The vitreous may become fluid and the chances of intra-ocular hemorrhage be increased by the same degenerative changes which cause the lens to atrophy.

Diabetes in India.—Glycosuria is frequent among rich elderly natives in Calcutta, many of whom are fat and indolent and immoderately fond of sweetmeats. Dr. Norman Chevers states that he has heard of several fatal cases of carbuncle in such diabetic patients. Writing in 1871, the editor of the *Indian Medical Gazette* remarked, that he believed that "among the upper and middle classes of natives in Calcutta, almost every family had lost one or more of its members from diabetes."

Poem of the Occasion.—The following has been sent us by a delegate:

There was once a great medical meeting
To arrange to give Europe a greeting;
Said they all, Well, we guess
We can kick up a mess,
So each one for his State began bleating.

Clinical Department.

STRICTURE OF THE URETHRA FOLLOWING MASTURBATION—INTERNAL URETHROTOMY—RECOVERY.

Dr. William Stone Torrey reports the case of a young man seventeen years of age who consulted him concerning an acne of the face which he asserted was due to masturbation. Examination showed a redundant and constricted prepuce, a contracted meatus, and an organic stricture of the urethra. The stricture was located one inch above the meatus, and extended upward a distance of two and a quarter inches. Its calibre was 25 mm., the normal calibre of the urethra being 34 mm. Circumcision was first performed, and when the wound had healed an Otis' urethrotome was introduced and dilated up to 34 mm., and the stricture was divided along its whole extent. Previous to the operation one-half drachm of a four per cent. solution of cocaine was injected and allowed to remain for about five minutes. The subsequent incision of the meatus and division of the stricture were accomplished without the slightest pain to the patient. The stricture was tough and fibrous, and was remarkable in its extent and consistence, as masturbation was the sole cause, the patient never having been the subject of a gonorrhœa.

THE CAUSE OF CORNEAL OPACITY FOLLOWING INSTILLATIONS OF COCAINE.

Dr. J. Craft, of Cleveland, O, offers an explanation of the evil results sometimes observed to follow the continued employment of cocaine after operations upon the subconjunctival tissues. He recalls the fact that the drug acts not only as a local anæsthetic but also as an excitant of the vaso-motor nerves, causing a marked depletion of the vessels of the part. "Now I can readily see that in an operation upon an eye in which the conjunctiva is healthy and its vessels scarcely discernible, this second action might be overlooked. And the repeated application of cocaine, to relieve any pain subsequent to the operation, might occasion such absolute depletion of the vessels as to produce turbidity, and finally even necrosis of the cornea from lack of nutrition. Atropine instilled into the eye reverses this state of affairs; vaso-motor irritability is overcome, reaction ensues, and the turbidity of the cornea clears up. Such, I conceive, from my experience with cocaine, is the cause of the unpleasant effects recently reported." Dr. Craft suggests that the artificial production of anæmia may be prevented, without impairment of the anæsthetic effect, by the addition of a little atropine to the cocaine solution.

TWO CASES OF ACUTE MYRINGITIS RELIEVED BY COCAINE.

Dr. B. J. Baldwin, of Montgomery, Ala., has recently seen two cases of acute inflammation of the membrana tympani which were speedily and effectually relieved by instillations of cocaine. The first case was that of a young lady who had suffered intensely for two days, obtaining no relief, from any of the ordinary remedies. There was a blister the size of a hemp-seed in front of the umbo. The Doctor had refrained from using cocaine, relying upon the assertion of Knapp that the drum-membrane was unaffected by this drug. However, he determined to try it at last, and was no less delighted than astonished to find the pain entirely relieved in six minutes after two applications. The blister disappeared and the ear was well in four days. The second case was that of a man, twenty-four years of age, an inspection of whose drum-membrane showed a tense, yellowish, transparent blister involving the posterior and superior portions. This disappeared in two days without having ruptured. The patient suffered agony for a few hours until a cocaine solution could be obtained, but within seven minutes after the instillation of a few drops of a four per cent. solution was entirely free from pain, and remained comfortable under repeated applications of the drug during the three subsequent days of active inflammation. Dr. Baldwin recognizes that two cases are not enough to base any positive conclusions upon, but he maintains that they are amply sufficient to controvert Knapp's statement to the effect that cocaine will not anæsthetize the drum-head.

MORE FAILURES WITH CHLOROFORM IN THE TREATMENT OF TAPEWORM.

Dr. Charles G. Duncan, of Socorro, N. M., writes that he has met with three failures in the past year in the use of chloroform in tapeworm. The mixture which he employed was as follows: Chloroform, one drachm; castor-oil, two ounces; croton-oil, one-half drop; mucilage of acacia sufficient to make an emulsion. The remedy was given after a fast of from twenty-four to thirty hours, and in no case was the entire worm expelled. The Doctor subsequently cured these and several other cases with the mixture of pomegranate bark, pumpkin seed, ergot, male fern, and croton-oil, as given in The Medical Record of July 12, 1884.

COCA IN PHTHISIS.

Dr. J. Blake White, of 941 Madison Avenue, states that he has for several weeks been testing the effects of coca in phthisis, and the results thus far obtained tend to confirm his belief in the therapeutic value of the drug in this and other wasting diseases. "Prescribed in some cases of advanced phthisis associated with great physical depression it exerted a wonderful tonic effect, substituting a cheerful and hopeful state for one of despair, and in proportion establishing an improved condition of health. In some cases in which night-sweats were quite profuse the remedy seemed to have exercised a controlling influence. A more refreshing repose and a better appetite were observed in patients who had taken the wine of coca for a week or more, when prior to this treatment insomnia and anorexia were painful symptoms." Dr. White adds that coca is now being thoroughly tested in his service in Charity Hospital, and he hopes to be able to supplement this notice with a more full report concerning the value of the drug in the management of consumption.

RECOVERY FOLLOWING VERY RAPID CARDIAC ACTION IN AN ADULT.

Dr. Walter F. Morgan relates a case of puerperal convulsions occurring in a primipara, an inmate of the Kansas Home for the Friendless. There were about forty distinct paroxysms, with the usual biting of the lips and tongue. There was stertorous breathing, the patient was profoundly insensible, and the axillary temperature was 103° F. "The peculiarity of this case was that, although the pulse was as high as 180 per minute, and was very weak and fluttering, the patient finally recovered. Ringer states that in febrile diseases, when the adult pulse reaches 160, the patient almost always dies. In deference to this statement and influenced also by a previous history of defective heart action and by the symptoms as a whole, I gave an unfavorable prognosis."

How the French give Castor-oil to Children.—A French method of administering castor-oil to children is to pour the oil into a pan over a moderate fire, break an egg into it, and stir up; when it is done, flavor with a little salt or sugar or currant-jelly.

Progress of Medical Science.

Hydrophobia following a Rat-bite.—A young sailor, aged twenty years, engaged in the coasting trade in France, was bitten during sleep, some time in December, 1883, by a large gray rat, first in the upper lip, and then four times in the left hand. The wounds healed quickly and kindly, not having even bled. But after a fortnight swelling came on in the bitten hand, combined with fever and diaphoresis. These passed off, but returned again in the course of a few weeks, to be followed, in January, by a sudden appearance of purpuric spots on the bitten arm, the thorax, and the back. These disappeared under the influence of collodion and acid drinks, but during the whole time the patient was subject to nervous dysphagic attacks, during which the face became congested, a constriction was felt at the throat, with whistling respiration from closure of the glottis, and he could neither speak, swallow, nor breathe freely. On February 27th he came under the care of M. Millot-Charpentier, who at once thought of hydrophobia, an idea which had not been present to the patient's mind at all. He was then very anæmic, with purpuric spots, a daily recurrence of the nervous symptoms, and an attack of fever every three or four days, lasting for some hours. He was ordered a tablespoonful of a one per cent. solution of permanganate of potash three times a day, nine grains of quinine every evening for fourteen days, and afterward on alternate evenings, and once a week a saline purge in some bitter infusion, with nitrogenous diet, exercise, and medicinal doses of alcohol. In the course of the next month he had only two severe attacks, but on March 28th a small tumor, of the size of an egg, and of a violet color, appeared in the region of the last rib on the injured side, accompanied by more ecchymosed spots. With this was combined excessive muscular weakness, so that, when seated, he was unable to rise without assistance. The treatment was continued with good results; the condition gradually improved, and in November he could be looked upon as cured. While the symptoms had a great resemblance to those of hydrophobia, they were also very like those of snake-bite, especially the purpura, the muscular weakness, and the great anæmia; and the case shows the connection which exists between different forms of animal poison introduced by means of a bite.—*The London Medical Record*, May 15, 1885.

Hernia of the Lungs into the Neck.—Surgeon-Major Knox describes two cases of displacement of the lung into the neck. The first occurred in a thin, delicate man, aged twenty-two. He had been healthy up to December, 1882, when he was admitted into hospital with bronchial catarrh, and remained one hundred and forty-six days under treatment. In February, 1884, while on the march, he had a violent fit of coughing, and felt something give way in the left side of the neck. After a short rest he walked back to camp, and discovered a tumor above his left clavicle, of the size of a hen's egg. The man continued on duty until June, 1884, when he presented himself at hospital complaining of slight pain in the chest, with dyspnœa on exertion and dry cough. The tumor was examined, and found to be soft and compressible. On auscultation respiratory sounds were audible over it, accompanied by small, dry crackling râles. The left lung was emphysematous. The patient remained in the hospital until December, 1884, during which time the hernia increased to the size of a large orange, but the general condition remained the same. The second case occurred in the practice of Dr. Wilkin. The patient was an Indian, who was admitted into hospital suffering from fever and general debility, and who frequently had attacks of asthma. Six days afterward the man died suddenly from syncope, about half an hour after returning from the latrine. At the post-mortem examination the left lung was found to beemphysematous, especially along the anterior border and at the apex. The right lung was emphysematous on the anterior border; the apex was protruded beneath the clavicle into the neck, and was dilated into a translucent tumor, about the size of a man's fist, in which most of the alveolar structure of the lung had disappeared.—*London Lancet*.

Syphilis and Tabes.—Professor Eulenburg, of Berlin has published an article on the question, so much discussed of late years, concerning the relation between syphilis and locomotor ataxia (*Virchow's Archiv*, January, 1885). The following propositions represent the views which he now entertains on the subject: 1. There is an absolute and relatively somewhat large percentage of tabetic patients who have suffered from syphilis; the number of these is considerably larger than was generally admitted until within the last few years. 2. The exact relation of syphilis to tabes is uncertain. Probably in most cases syphilis acts only as a debilitating predisposing cause, like many other agencies—such as heredity, mental affections, etc.; but perhaps in some instances syphilis is the direct cause of tabes. 3. At any rate, syphilis can hardly be considered to be the most frequent and most important cause of tabes. 4. The cases of tabes which have been preceded by syphilis present no constant and characteristic symptoms, nor any peculiarity in their course, by which they can be distinguished from other (non-syphilitic) cases. 5. As regards prognosis and treatment, also, there is no clear and characteristic distinction between the two classes of cases. Those with syphilitic antecedents may in certain circumstances improve, perhaps even recover, either with or without specific treatment; while, as a rule, such treatment is either of no avail or only attended by temporary benefit. 6. The investigation of the etiology and pathogeny of tabes in relation to syphilis, which has been prominent of late years, has not yet afforded any definite solution of the question; nor, according to the experience of the author, can the discussion be said to have yet led to any permanent result as regards the best treatment of tabes.

Is Tuberculosis Transmissible through the Sputum?—Sirena and Pernice have carried out a series of experiments concerning the transmissibility of tuberculosis through the agency of tubercular sputum. The animals employed in their studies were rabbits and guinea-pigs. Their conclusions may be summed up as follows (*Gazet. degli Ospitali*): The liquid obtained by the evaporation of tubercular sputum is always free from Koch's tubercle bacillus; therefore, when placed upon the cornea, injected into the subcutaneous cellular tissue, or into the peritoneal cavity, it does not give rise to tubercle. 2. Tubercle bacilli do not rise in an atmosphere moving over moist tubercular sputa, even when the sputa are very rich in bacilli. 3. The respiration for several hours, or even for several days, of tubercular exhalations does not give rise to phthisis in animals. 4. Animals obliged to respire an atmosphere charged with the dried dust of tubercular sputum do not catch phthisis. 5. The subcutaneous injection of tubercular sputum produces for the most part a specific abscess, as is proved by the presence of the tubercle bacillus in the pus; then, after a variable period, it produces tuberculosis of the abdominal and thoracic organs. 6. Injection of tubercular sputum into the peritoneum produces at first local and then general tuberculosis, capable of successive inoculations in animals. 7. The injection of solutions of tubercular sputum into the trachea, even in animals affected with bronchopneumonia, does not cause a specific infection, but for the most part a septic croupous pneumonia, characterized by the existence of micrococci in the exudation.

Graduation of a Chinese Lady.—Miss Hai-Mè King, a native of China, received the degree of M.D. at the Commencement of the Women's Medical College on May 29th.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 4, 1885.

THE RESULTS OF COLLECTIVE INVESTIGATION REGARDING OLD AGE.

WITH every year the average duration of life is increased, and we have more old people on our hands. Naturally, the question becomes of increasing interest, how shall we secure a healthful old age, and how can we prolong in comfort this senility.

Some curious information regarding this subject, though more especially regarding what may be called "centenarianism," has been published by a gentleman of Syracuse, N. Y., who, we are informed, has collected the histories of 10,000 people that have passed the age of one hundred years. According to this authority, the United States leads in centenarian longevity, while Connecticut is ahead among the States. As to sex, women; as to occupation, soldiers, sailors, and farmers are the longest lived. Among the professions, 100 ministers, 30 doctors, and 10 lawyers reached their centennial.

Of more practical and scientific character are the statistics regarding longevity obtained by the British Collective Investigation Committee. These are based upon over five hundred returns, and relate to persons who have reached or passed the age of eighty.

Professor Humphrey, of Cambridge, has given some interesting deductions based upon these returns in an oration recently delivered before the Medical Society of London.

The first requisite for longevity must be an inherent quality of endurance, a something which is inborn and perhaps inherited. It is noticeable that the phthisical taint does not necessarily lessen the capacity for longevity. Among five hundred aged persons, phthisis appeared in fathers, mothers, brothers, or sisters of eighty-two, that is, in about seventeen per cent. In one case both father and mother were phthisical.

A second requisite for long life is freedom from exposure to casualties. It is on this ground, in part, that more women than men reach extreme age. Other reasons, however, are, perhaps, a greater natural vitality, since even in early life the mortality is less among females than males. It does not seem to be proved by the data collected that short and small men and women have any advantage over those who are taller and larger. The average height of old Englishmen is 5 ft. 6 in., that of women, 5 ft. 3 in.

Professor Humphrey would limit quite sharply the changes which normally occur in old age. They are quantitative rather than qualitative. There is a diminution in material and force, with perhaps a slight increase in the oily matter of the tissues—all other changes are pathological.

Among the most marked of senile changes are those of the bones. These lose in weight, but not necessarily in size; indeed, they may even increase in size by a sub-periosteal ossification. The interior of the bones becomes softened and filled with marrow; the walls become thinned. The ends of the bones are particularly affected in this way, and hence the liability of the bones to fracture at these parts. The alveolar processes waste away, so that in men above eighty the number of teeth is only six, while in women it is but three. The cranium generally becomes thinner and lighter. In some cases, however, the skull-walls are actually increased in density and thickness by the osseous deposits on the interior of the brain-case.

Contrary to a generally received view, the cartilages of healthy old people do not calcify and harden, but remain elastic. They, however, undergo some atrophy, which accounts for the decrease in height.

In the same way Professor Humphrey believes that calcification of arteries is not a process normal or common in advanced age. Among 382 returns relating to the pulse, it was found incompressible in only 72. In 362 returns, the arteries were found knotty in only 40. We cannot, however, place very much dependence upon such data.

The rate of the heart-beat in old age has been said by some physiologists to be increased, by others to be diminished. The Collective Investigation shows that there is not much change. From the age of eighty to ninety it averages 73–74 in men, 78–79 in women. The respirations are a little increased in frequency, especially in women. Urinary troubles are a well-known source of discomfort and suffering among old people. They do not, however, necessarily attend the decline of life. Among 157 males from eighty to eighty-five years of age, only 6 had any disease of the prostate or bladder. In the next half decade, however, the proportion was greater.

In old people wounds are known either to heal rapidly or to slough. The reparative process is often as rapid as in the young.

Sir Henry Thompson in a recent article on "Diet in Relation to Age," has called attention to the harm that comes from attempts to over-feed old people. They are injured, he truly says, by the solicitous relatives, who think that in feeding there is sure help for the waning strength. The old need a light diet to correspond with the lessened work and slower nutrition and waste of their tissues.

NITROGEN IN PHTHISIS.

THE first physician who ever studied the medicinal properties of nitrogen was an American, Dr. Winthrop Saltonstall (New York, 1796), who evidently got his ideas from his teacher, Dr. Mitchell. Dr. Saltonstall's essay was of a fanciful character and added nothing to practical knowledge. Another and more valuable contribution was made by Dagoumer in 1816. Subsequently Nysten, a co-worker of Bichat, injected nitrogen into the veins of

animals, and found it to have a sedative action upon the heart. In 1829 M. Marc, in the "Dictionnaire de Therapeutique," cites cases in which inhalations of nitrogen were used with good effect in phthisis.

Demarquay in his "Pneumatologie Médicale," 1866, describes two series of experiments with nitrogen. Injected subcutaneously, or into the peritoneum, it caused an increase in the exhalation of oxygen and carbonic acid. Applied locally to wounds it had some slight sedative effect.

Of late years a number of carefully conducted experiments have been made in order to determine the exact status of nitrogen as a remedy in pulmonary troubles. The names of Valenzuela, Treutter, Siefermann, Mermagen, Krüll, Kohlschulter, are associated with these experiments. Dr. Treutter, of Blasewitz, has recommended for some years inhalations of rarefied or partly deoxidized air in phthisis. In 1879 he ventured the opinion that the nitrogen was actively beneficial. Mermagen has affirmed this view with much more positiveness, and gives experimental data in support. Siefermann in a review of the subject (*Gaz. Méd. de Strasb.*, January 4, 1885, *Lond. Med. Record*, May, 1885) states that when patients are made to breathe air to which nitrogen has been added in the proportion of two to seven per cent., certain well-marked symptoms are observed, and these are repeated so constantly as to justify the belief that they are to be referred to the inhalations. With the first inspirations the patients assert that they breathe more easily, the dyspnœa diminishes, and a general sensation of well-being supervenes. The pulse becomes small, often filiform, from contraction of the radial artery. The patients—weak, anæmic, and nervous—experience, during the operation, vertigo, a sensation of weakness and pressure on the head, which may occasionally lead to syncope. The symptoms only are observed in the first two or three sittings.

According to Krüll and Mermagen the best therapeutical results are obtained when from two to seven per cent. of nitrogen is added to the atmospheric air. Inhaled in this proportion night-sweats cease, apical dulness disappears, the appetite improves, colliquative diarrhœa is relieved, and sleep produced. All authors agree that the nitrogen has some soporific and sedative effect.

The physiological effects of inhaling air containing an excess of nitrogen at ordinary barometric pressure have been studied by Legallois, who shows that less oxygen is absorbed and less carbonic acid exhaled, a lowering of respiratory function occurring. But, besides this, there seems to be a specific sedative effect produced by the nitrogen. It is to be recommended, therefore, in inflammatory lung troubles, especially in early phthisis.

THE PATHOLOGICAL ANATOMY AND TREATMENT OF SPINA BIFIDA.

THE pathology and treatment of spina bifida are subjects still involved in some uncertainty, and the physician who is called to treat a case always feels that he must exercise the greatest judgment and circumspection. Spina bifida is a rare condition, fortunately, yet mortality rates show that in all probability about one child in every fifteen hundred is born with such defect. An interesting report upon the subject has recently been made by a committee of the London Clinical Society, Mr. R. W. Parker, being chairman. This committee made a special study of the numerous specimens illustrating spina bifida in the Museum of the College of Surgeons.

As regards the pathological anatomy their conclusions were that spina bifida presents three different forms. The first and most frequent is that in which there is a protrusion of the spinal meninges together with the spinal cord and its appertaining nerves (meningo-myelocele); in the second form, which stands also second in frequency, there is a protrusion of the membranes only (simple meningocele); in the last and rarest form there is a protrusion of the membranes together with the spinal cord, the central canal of which is dilated so as to form the sac cavity, the innermost lining being constituted by the expanded and atrophied substance of the cord (syringo-myelocele). A careful dissection is often necessary to distinguish between a simple meningocele and a syringo-myelocele. The committee make the important statement that in the ordinary form of spina bifida (meningo-myelocele) the spinal cord traverses the wall of the sac unchanged, giving off its nerves regularly as it lies in the sac wall. The descriptions of pathological anatomy which imply that the nerves are sent into the sac from an intraspinal portion of the cord are therefore incorrect. The central canal of the cord also, in these cases, continues on through the cord as it runs in the sac wall, and is not unclosed or dilated as has been sometimes asserted.

The theory which best explains the pathological anatomy of spina bifida is that which assumes a primary defect of development of the mesoblast, from which the structures closing in the vertebral furrow are developed. Spina bifida, is not, therefore, primarily a neural defect.

The question of the proper treatment of spina bifida is sometimes a very difficult, and is always a sufficiently unpromising one. In 1882 there were 649 deaths from this condition in England and Wales, 612 of these occurring in infants under one year of age Undoubtedly this represents the majority of all the cases occurring during that year. Every mode of treatment has secured some successes, but perhaps, up till lately at least, expectant and symptomatic measures have been best. In 1881 Dr. James Morton reported a series of 27 cases, in which he claimed to have obtained 21 cures out of the total operated upon. His method of treatment consisted in injecting, at intervals of seven to ten days, half a drachm of a solution made by dissolving ten grains of iodine and thirty of iodide of potassium in an ounce of glycerine. The committee of the Clinical Society reported that their collected tables showed a percentage of successes by Morton's treatment of from fifty to sixty. The higher mortality (of forty to fifty per cent.) was due to the fact that the method was adopted in unsuitable cases. Despite it, the committee advocated the plan of treatment by injection, and against that by excision or ligature.

REGULATING MEDICAL PRACTICE IN PENNSYLVANIA.

THE Report of the Committee on Regulating the Practice of Medicine, of which Dr. Traill Green is Chairman, was made to the Pennsylvania State Medical So-

ciety, and after some debate was adopted by a large majority.

The report is an admirable and judicious presentation of the subject, and deserves the attention of all interested in promoting the standing of the profession. The two main points made were these: first, that laws regulating the practice of medicine, by compelling registration, are ineffectual, so long as "the diploma of any legally chartered medical college is made the only requirement for registration; second, that the power of license to practise medicine should be taken from the colleges and be vested in a single State Board."

The present registration law of Pennsylvania is not a satisfactory one, nor do any of the registration laws, as yet, do all that can be expected from wise legislation.

The Committee of the Pennsylvania Society is empowered to draw up a bill which will embody the views above presented. This bill, after approval by the Society, will be brought before the Legislature. We trust that Pennsylvania will be more successful than New York has been in piloting between the Scylla of quackery and the "pathies," and the Charybdis of the medical colleges.

AN EASILY KILLED BACILLUS.

Dr. Robert Koch has shown that the cholera bacillus is rather a tender plant, and can be destroyed without any great difficulty. Drs. Nicati and Rietsch have more recently (*Rev. d'Hygiene*, May 20) contributed further facts of importance regarding this subject. These observers found, first of all, that the bacillus lives in the human body on the average only six days from the date of the attack. After this period the individual contains no specific germs, and is not a contagion bearer. In some cases the bacilli were gone in four days; in two cases a few were found on the eleventh day.

As Koch showed, the cholera bacilli are killed after twenty-four or thirty-six hours by the bacteria putrefaction. They are also killed by drying, by heat to 140° F., and by many alkalies and acids. In moist earth the bacillus lives from fourteen to sixteen days; in distilled water, twenty days; in sea-water, sixty-four to eighty-one days; in bilge-water of an iron ship, thirty-two days.

It appears that under the most favorable conditions the comma bacillus dies easily, and we can hardly understand how its delicate constitution survives a European winter, as it undoubtedly does.

Asylum Tragedies.—News comes from Marseilles of a sad occurrence in the Saint Pierre Lunatic Asylum. A keeper put two patients each in a separate bath, left them, and went to breakfast. One of the lunatics got out of his bath, during the absence of the keeper, and turned on the tap of hot water into the bath of the other. When the keeper returned he found that the unhappy creature had been scalded to death. In the Asylum at Sébon, near Dinan, a lunatic suddenly assaulted one of the attendants, another attendant who started to the rescue was attacked by a second lunatic. Both the attendants were knocked down and one mortally wounded. The two homicides then started for the central building with the intention of killing the superintendent. They were, however, captured and secured.

News of the Week.

Blonde Hair and Exophthalmic Goitre.—Dr. A. D. Rockwell writes in regard to the relation of exophthalmic goitre and auburn hair that "my own experience leads me to believe that Dr. Neal's cases were coincidences. Out of more than twenty exophthalmic patients that I have seen and treated, only a small minority had auburn hair. Black and brown greatly predominated."

Prevention of Cholera.—The City Council of Chicago has taken an important step toward insuring the perfect sanitation of the city by allowing the Health Department a special fund of $100,000. Of this amount $12,000 is to be expended toward increasing the force of inspectors, by which 50,000 houses will be inspected by September 1st. The sum of $40,000 will go toward the cleaning of alleys, and the remainder will be held for an emergency fund.

Dr. W. G. Bullock, of Savannah, Ga., born in 1811, a graduate of Yale College and of the University of Pennsylvania, Class of '33, is dead. He was frequently President of the Georgia Medical Association, and was corresponding member of many medical bodies.

Dr. Noël Gueneau de Mussy, whose death occurred in Paris recently, was well known as a physician and a contributor to medical literature. He married an English lady and frequently visited England, where he was well known and greatly liked by his medical confrères.

Professor Gerhardt, of Würzburg, has been placed first in the list of names of candidates for the Chair of Medicine in Berlin University, as successor to the late Prof. Frerichs.

Over-study and the Teeth.—The latest fad among Parisian physicians who are worried about the over-education of children is that it causes a deterioration of the teeth.

Vivisection in England.—The usual annual reports showing the number of experiments performed on living animals in Great Britain and Ireland during the year 1884 have been issued. Out of a total of 454 experiments, 170 were merely inoculations; of these inoculations, 24 were performed for the purpose of medico-legal inquiries, and involved the death of three frogs and six mice by strychnine; in 10 other cases the experiments were made in order to infect fish with a species of fungus very fatal in certain streams, and five experiments led to the death of about thirty minnows and sticklebacks, which died when placed in distilled water. In 47 other experiments, in which the animal operated on was allowed to recover from the effects of the anæsthetic, the animals subsequently suffered from partial paralysis unattended by actual pain. In 220 other cases the animal was not allowed to recover consciousness.

An Interesting Debate.—At the annual meeting of the British Medical Association at Cardiff this year, in connection with the Section of Pharmacology and Therapeutics, there will be a special debate on Anæsthetics, in which Dr. Dujardin-Beaumetz (Paris), Professor John Chiene (Edinburgh), Dr. Dudley Buxton, Mr. Wood-

house Braine, Mr. Bailey, Mr. Marcus Gunn, and others, will take part. There will be an exhibition of apparatus, and Dr. Buxton and Dr. Stockman (Edinburgh) will illustrate the action of the various drugs on the frog's heart. The subject of local anæsthesia will be discussed, and Dr. Karl Koller (Vienna), the introducer of cocaine, has promised to attend.—*British Medical Journal.*

A Medical School at Oxford at Last.—Our English exchanges are congratulating themselves on the fact that steps are now in progress which will restore the medical faculty at Oxford, arrange the classes necessary for the first two years of medical and scientific subjects in the curriculum, and provide reasonable regulations for examination for the titles of M.B. and M.D.

The Acquittal of Lucille Yseult Dudley for homicidal assault upon Rossa furnishes an exquisite illustration of the workings of our lunacy law. The woman is epileptic and has had several attacks of mania. She evidently does not possess a healthy mind, nevertheless it was unquestionably shown that at the time of her shooting Rossa she knew very well the "nature and consequences of her act." It was not done in an outburst of maniacal rage or epileptic frenzy. According to law, therefore, she should have been convicted. Nevertheless the jury saw deeper than the letter, and unconsciously assumed the medical position that the act was tainted with insanity, and was the offspring of a diseased brain.

New York Polyclinic.—Dr. M. Allen Starr has been made a Professor of Diseases of the Mind and Nervous System in the New York Polyclinic.

A Possible Explanation of Ferrán's Cholera Inoculations.—A recent cable report to the *Herald* gives the following statistics of Ferrán's work at Alcira: "The population of Alcira is 20,000 or 22,000. Of these the correspondent finds 9,100 inoculated, 7,500 of whom were reinoculated. Rich and poor and the middle class have all submitted to be vaccinated. Altogether 320 cases of cholera have been recorded at Alcira. Of these 130 died and 138 recovered, while 52 are under treatment. The deaths of non-inoculated persons were 120, against 7 inoculated and 3 reinoculated. Of the inoculated and reinoculated 20 had the disease and were cured." Thus in the halt of the population which was inoculated the number of cholera cases was 30, and of deaths 10, against 290 cases, with 120 deaths, among the non-inoculated. Assuming these figures to be approximately correct, we may take the smaller percentage of cases and deaths among the inoculated to represent the prophylactic effect of a feeling of security caused by the operation. In other words, inoculation may be interpreted as a kind of faith-preventive. A factor of importance, also, is probably the inoculation of the more intelligent and careful. Altogether, we can see, as yet, nothing in the least demonstrative in the results of Ferrán's inoculations.

The College of Surgeons.—The younger members of the Royal College of Surgeons are clamoring for a reform in that august body, but the members of the Council, at least the majority of them, are obdurate, and do not see the necessity of a change. Nearly seventeen thousand of the twenty-five thousand medical men in the "Register" are members of the College of Surgeons, but of fellows there are only about twelve hundred. Only fellows are eligible for election to the Council, and of them only such of fourteen years' standing as are in the actual practice of their profession as pure surgeons. There are twenty-four members of the Council, each of whom retains his seat for eight years and is eligible to a re-election. Only fellows have a vote in the election of councillors, and they must attend personally at the college to record their vote. The practical working of this rule is, of course, that only a minority of the fellows vote, usually not more than two or three hundred, or less than one-fourth of the total number. All power is vested in the Council, and the natural consequence is that they elect a large proportion of their own number to lucrative examinerships. Members have no power and no privileges. It is therefore not surprising that the fellows, and still more the members, of the college are in open rebellion against the existence of a close corporation of this sort. They have hitherto accomplished little, but are now trying to prevent the Council from obtaining a new charter.

The Meeting at Chicago of the New Orleans Committee of the American Medical Association on the International Congress.—The Committee in question, consisting of the original committee and gentlemen representing each State and Territory, the District of Columbia, Army, Navy, and Marine Hospital Service, held a meeting, June 24th and 25th, at Chicago, pursuant to call. Twenty-nine members were present out of the whole forty-five, as follows: Dr. R. Beverley Cole, of California; Dr. John V. Shoemaker, of Pennsylvania; Dr. D. A. Linthicum, of Arkansas; Dr. George A. Ketchum, of Alabama; Dr. A. Y. P. Garnett, of Washington; Dr. William E. Duncan, of Dakota; Dr. Robert Battey, of Georgia; Dr. E. P. Cook, of Illinois; Dr. F. W. Beard, of Indiana; Dr. D. W. Stormont, of Kansas; Dr. W. H. Wathen, of Kentucky; Dr. A. H. Wilson, of Massachusetts; Dr. A. R. Smart, of Michigan; Dr. N. F. Essig, of Missouri; Dr. John S. Lynch, of Maryland; Dr. George F. French, of Minnesota; Dr. William Pierson, of New Jersey; Dr. J. W. S. Gouley, of New York; Dr. E. Eliot, of New York; Dr. X. C. Scott, of Ohio; Dr. I. Minis Hays, of Pennsylvania; Dr. F. L. Simm, of Tennessee; Dr. J. W. McLaughlin, of Texas; Dr. E. F. Upham, of Virginia; Dr. Nicholas Senn, of Wisconsin; Dr. G. Baird, of West Virginia; Dr. John S. Billings, of Washington, U. S. Army; Dr. John B. Hamilton, of Washington, U. S. Marine Hospital Service.

The resignation of Dr. Austin Flint was read and accepted. Dr. J. W. S. Gouley, of New York, was appointed in his place.

Dr. Battey offered a resolution: "That it was the sense of the Committee that in the absence of members from its meeting, the vacant places should be filled, if at all, by members of the American Medical Association for the vacant States or Government departments." This, with an amendment refusing to receive proxies, was adopted.

The Committee then proceeded to ballot for permanent chairman and secretary. On the first ballot Dr. Lynch, of Baltimore, and Dr. Cole tied. Dr. Cole was elected on the third ballot by a vote of 17 to 11. Dr. Lynch was

made vice-chairman. Dr. John V. Shoemaker was then elected permanent secretary, receiving 16 ballots out of 26.

A sub-committee was then appointed to prepare a revision of the rules and preliminary organization of the Ninth International Medical Congress. The committee consisted of Dr. Scott, of Ohio; Dr. Wathen, of Kentucky; Dr. Billings, U. S. Army; Dr. Shoemaker, of Pennsylvania; Dr. Hamilton, Marine Hospital Service; Dr. Upham, of Vermont; Dr. Gouley, of New York; Dr. McLaughlin, Texas; and Dr. Linthicum, of Arkansas.

A resolution was passed that fifteen members should form a quorum at future meetings.

At the evening session Dr. X. C. Scott reported that the sub-committee had been at work, but required an extension of time. Dr. Garnett presented an opinion received from the Hon. Samuel J. Randall relative to the legal status of the present Committee. The opinion was to the effect that the Association had not exceeded its powers in the appointment of the present Committee.

At the meeting of the Committee on the next day, June 25th, the sub-committee made its report. They recommended a decrease in the number of sections from nineteen to sixteen. The following gentlemen were selected as chairmen: Histology, Prof. Stanford E. Chaille, New Orleans; Anatomy, Prof. Joseph Leidy, Philadelphia; Physiology, Prof. J. C. Dalton, New York; Pathology, Dr. Francis Delafield, New York; Practical Medicine, Dr. J. M. Da Costa, Philadelphia; Surgery, Dr. D. W. Yandell, Louisville; Gynecology, Dr. Robert Battey, Rome, Ga.; Ophthalmology, Dr. E. Williams, Cincinnati; Otology, Dr. C. J. Blake, Boston; Dermatology, Dr. W. O. Hardaway, St. Louis; Laryngology, Dr. J. N. Mackenzie, Baltimore; Public and International Hygiene, Dr. H. A. Johnson, Chicago; Collective Investigation, Nomenclature, Vital Statistics, and Climatology, Dr. N. S. Davis, Chicago; Military and Naval Surgery and Medicine, Dr. David L. Huntington, U.S.A.; Practical and Experimental Therapeutics, Dr. H. C. Wood, Philadelphia; Diseases of Children, Dr. J. Lewis Smith, New York.

By the above arrangement the sections on Dental and Oral Surgery, Nervous Diseases and Psychiatry, Obstetrics, and Medical Education and Legislation are left out. A section on Histology is established. Dr. A. Jacobi is removed from the presidency of the section on Children's Diseases. We learn that among the gentlemen removed from all official connection with the proposed Congress are: Drs. A. L. Loomis, R. F. Weir, A. Jacobi, T. Addis Emmet, C. R. Agnew, P. F. Mundé, A. H. Smith, C. S. Bull, H. Knapp, D. B. St. J. Roosa, S. Sexton, Allan McL. Hamilton, L. Johnson Ripley, Wm. H. Draper.

The Committee adjourned to meet in St. Louis the first Monday in May, 1886.

The International Medical Congress and the Medical Profession of Philadelphia.—A meeting of the members of the medical profession of Philadelphia concerned in the organization of the International Medical Congress of 1887, was held at the hall of the College of Physicians, on Monday, June 29th, Dr. Alfred Stillé in the chair. Dr. David W. Yandell, of Louisville, was present by invitation.

After hearing a report of the proceedings of the new Committee, at the meeting held in Chicago last week and after considering the changes in the organization which were made, including the restriction of the scope of the membership, by which a large proportion of the profession of the country would be excluded from the Congress, the following preamble and resolution were unanimously adopted:

Whereas, Certain serious changes have been recently effected in the preliminary organization and rules for the International Medical Congress of 1887, it has seemed desirable for the members of the General Committee and the officers of the Sections resident in Philadelphia to meet for consultation; and

Whereas, It has appeared that these changes are inconsistent with the original plan, and detrimental to the interests of the medical profession in America, and of the International Medical Congress; therefore, be it

Resolved, That we, the undersigned, consider that our duty to the profession and to ourselves requires us to decline to hold any office whatsoever in connection with the said Congress as now proposed to be organized.

Reviews and Notices.

A Manual of the Medical Botany of North America. By Laurence Johnson, A.M., M.D., Lecturer on Medical Botany, Medical Department of the University of the City of New York, etc. New York: Wm. Wood & Co. 1884.

This volume constitutes the December number of Wood's Library for 1884. It is a work valuable alike to student and practitioner, for it contains precisely the kind of information regarding the medicinal plants of North America, that is conspicuous by its absence from most text-books and almost all college lectures on materia medica. A valuable feature of this manual is found in the abundance of well-executed drawings and colored plates. The latter reflect high credit both upon Dr. Johnson, who designed them, and the publishers who had them faithfully reproduced. The work will be of decided assistance to medical men as a manual containing reliable botanical information. It is divided into two parts, the first of which deals with the essential elements of botany, and the second being specially devoted to a consideration of the medicinal plants of North America. The author has wisely refrained from giving a detailed description of all the medicinal species found in our country. But all the important ones have received ample attention.

ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE, for the Fiscal Year 1884.

BESIDES the regular official report the present volume contains a number of scientific and clinical communications, which give to it a permanent value.

KIRKES' HANDBOOK OF PHYSIOLOGY. By W. MORRANT BAKER, F.R.C.S., and VINCENT DORMER HARRIS, M.D. Lond. Eleventh Edition, with nearly 500 Illustrations. 2 vols. New York: William Wood & Co., 1885. Wood's Library of Standard Medical Authors.

A MANUAL OF HUMAN PHYSIOLOGY, INCLUDING HISTOLOGY AND MICROSCOPICAL ANATOMY, with Special Reference to the Requirements of Practical Medicine. By DR. L. LANDOIS. Translated from the Fourth German Edition, with Additions by WILLIAM STIRLING, M.D., Sc.D. 2 vols., 8vo. Vol. I., pp. 514. Philadelphia: P. Blakiston, Son & Co. 1885.

IT is an excellent sign of the times that so many thoroughly good text-books on physiology have of late been given to the American profession. Our students have too long been nurtured upon home works, which were both defective in method and provincial in tone. The translation into English of Hermann's and of Landois' treatises, the issuing of text-books by Foster, Martin, and Yeo; the rehabilitation of the standard works of Kirkes and Mapother, all indicate an interest in advancing physiology which cannot but react most favorably on medical practitioners.

There are now several almost equally good text-books on physiology in the market. Among the best, undoubtedly, is that of Kirkes, as enlarged and edited by Baker and Harris. Both these gentlemen have had experience in physiological teaching and writing, and their names are a guarantee that their book is brought up to the times. They have added a large number of new illustrations, besides remodelling many parts, and adding some new chapters. The present edition of Kirkes' Physiology is intended as a guide for students, "especially at an early period of their career," hence it does not deal with controvertible questions or go into minute details of purely scientific interest. For the practising physician who wishes to learn what is now accepted as established in physiology the volumes are well adapted.

There are also very good histological descriptions prefacing the physiology of the different organs. The printing and the illustrations are, with a few exceptions as to the latter, all that could be desired.

Professor Landois' large work on Physiology has already gone through several editions in a short space of time. It has also already been freely plundered from in the past few years, especially by English writers. The present translation is another tribute of a most creditable kind to its merits. Landois' Physiology is without question the best text-book on the subject of physiology that has ever been written, and fully deserves all its honors. Its aim has been to unite the scientific with the practical. The various vital phenomena of the human body are classified, analysed, and described in scientific order, and with minuteness and exactness. At the same time their bearing in medical practice is kept in view, and to each chapter is appended a brief description of the disorders which the normal mechanism is subject to.

We fear, however, that Professor Landois' work, though so complete and admirable, would utterly floor the average American medical student, whose mind is very apt at receiving impressions, but not at comprehending scientific relationships. And the present volumes, despite their practical appendices, might dismay him with their apparent eruditeness. It would be a benefit to the student ultimately, however, if he were compelled to drill over them, while the practitioner cannot but find them valuable.

Dr. Stirling has done his laborious work of translation well. He has also contributed a number of useful comments of his own, as well as increase the illustrations from one hundred and six to one hundred and seventy-six. The American publishers have done their work carefully. The type is clear—very much like that of the original—and the illustrations are also good. We trust that the book will become a familiar one to American physicians.

THE MEDICAL ANNUAL, AND PRACTITIONER'S INDEX. 1884-85. 8vo., pp. 428. Henry Kimpton, 82 High Holborn, London, W. C.

THIS annual contains a review of progress in general and medical science, notice of new inventions, facts about medical education, sanitary memoranda, a brief description of European health resorts, and statistical data regarding English medical societies, hospitals, etc.

LECTURES ON DISEASES OF THE NERVOUS SYSTEM, ESPECIALLY IN WOMEN. By S. WEIR MITCHELL, M.D. Second edition, revised and enlarged, with Five Plates. Pp. 287. Philadelphia: Lea Brothers & Co. 1885.

IN the present edition of this book the author has altered considerably some of the early lectures and has added others on the difficulties of diagnosis in hysterical diseases of joints, on the relations of hysteria to organic disease of the spine, and on hysterical disorders of the rectum. Dr. Mitchell records many facts of a character that are strange and unusual to the ordinary practitioner. All the more, his book is valuable to those who sometimes become puzzled by obscure nervous manifestations. Perhaps the author's experience is especially peculiar, in that he observes such severe manifestations of purely functional diseases among his patients. The record of a Miss B——, who showed almost every evidence of organic spinal disease including De R., but who was finally cured, is most important, as it has led to some statements that De R. may appear in hysterical paralyses. The probabilities are, however, that there was some true organic change in the nerves, if not in the cord. The various chapters in Dr. Mitchell's book have already been reviewed in these pages and need not be referred to again here.

JAHRESBERICHTE ÜBER DIE FORTSCHRITTE DER ANATOMIE UND PHYSIOLOGIE. Herausgegeben von DR. FR. HOFMANN und DR. G. SCHWALBE. Zwölfter Band. Literatur, 1883. II. Abtheilung. Physiologie. Pp. 490. Leipzig: Verlag von F. C. W. Vogel. 1885.

THE volume is a careful and critical summary of physiological and toxicological progress in 1883.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY FOR THE YEAR 1884. Pp. 408. New York: D. Appleton & Co. 1885.

THIS volume is in nowise behind its predecessors in interest. Among the contributions are papers by Drs. Thomas, Mundé, Taylor, Bozeman, and Lusk, of New York. A memoir of Dr. J. Marion Sims, by Dr. Van de Warker, of Syracuse, closes the work. Among the by-laws, which, with the constitution, are printed in the introduction, we note the following terse statement: "Any Fellow who shall neither attend nor present a paper for three successive years shall, unless he offers an excuse satisfactory to the Society, be dropped from fellowship." A modification of this rule might be of service to some of our local societies.

INSOMNIA AND OTHER DISORDERS OF SLEEP. By HENRY M. LYMAN, A.M., M.D., Professor of Physiology and of Diseases of Nervous System in Rush Medical College, Physician to Presbyterian Hospital, Chicago. 16mo, pp. 173. Chicago: W. T. Keener. 1885.

WE have examined this book with interest. The author very fully discusses the nature and cause of sleep. The latter, he thinks, must be sought "in the molec-

ular structure of the brain rather than in fluctuations of the blood-current." "Sleep must be regarded as the cause rather than the consequence of the so-called cerebral anæmia which obtains during sleep." His arguments in maintenance of this view are forcible and interesting. The causes of insomnia are treated of at length. Under the head of remedies is discussed the new hypnotic paraldehyde. The author regards it as a valuable addition to our Pharmacopœia. He gives it in doses of from forty-five to one hundred and sixty grains. Sixty grains is fair dosage. The chapter on the treatment of insomnia in particular diseases contains many practical hints. Interesting discussions on dreams, somnambulism, and hypnotism close the book. We can commend its graceful diction and logical style. It is a valuable contribution to medical literature on the subject of the relations of our mental and physical natures.

Insanity and Allied Neuroses, Practical and Clinical. By George H. Savage, M.D., M.R.C.P. With Nineteen Illustrations. Pp. 544. Philadelphia: Henry C. Lea's Son & Co. Clinical Manuals for Practitioners and Students.

Dr. Savage has not aimed so much to write a systematic manual for students, as to put on record the results of his large experience with insanity. As physician for twelve years in the Bethlem Hospital for the acute insane, London, and as a teacher at Guy's Hospital, his advantages have been exceptionally good, and his views, embodied in the treatise before us, will be consulted with great interest. Regarded as a clinical work, concisely and judiciously written, we find Dr. Savage's treatise to be a very satisafctory one. And imprimis, we must congratulate the author upon having written his work without giving a new definition of insanity; it is a remarkable evidence of literary self-control. Dr. Savage's "ideal classification" of the different forms of insanity is a rearrangement of old clinical terms. It is not adopted by the author himself, who divides insanity into a large number of clinical groups, and discusses them seriatim. Perhaps this is the most practical way, and it is certainly the easiest. We wish, however, that Dr. Savage had shown a little more courage in dealing with the question of classification, and had applied his synthetic powers and excellent judgment to the production of something better and more cohesive than "clinical groups."

The chapters on causation of insanity are particularly good, and we feel a pleasure in corroborating the conservative views that he expresses regarding the influence of heredity, education, intemperance, masturbation, etc., in producing insanity.

On taking up his different clinical groups, we find ourselves disappointed in reading the chapters on hysteria, hypochondriasis, and neurasthenia. The author seems familiar only with one phase of these complicated conditions. The chapters on general paralysis are evidently written *con amore*, and are among the best in the book. Especially good, also, are the chapters on idiocy and imbecility, and on the legal relationships of insanity and the responsibility of lunatics. There is not so full a description of the therapeutics of mental disease as could be desired

Dr. Savage writes in an attractive way, and, without making attempts at literary embellishment, he succeeds throughout in holding the attention of the reader. We trust he will have many thus to hold.

Elements of Practical Medicine. By Alfred H. Carter, M.D. Lond. Third Edition. New York: D. Appleton & Co. 1885.

Only a short time has elapsed since the issue of the last edition of Carter's "Elements," a sign that this practical little volume is appreciated by medical readers. As the work has undergone no noteworthy alteration since the second edition was published, it is unnecessary to repeat here what was then said regarding its merits and shortcomings.

Urinary and Renal Derangements and Calculous Disorders: Hints on Diagnosis and Treatment. By Lionel S. Beale, M.D., Fellow of the Royal Society and of the Royal College of Physicians, etc. 16mo, pp. 356. Philadelphia: P. Blakiston, Son & Co. 1885.

In this volume Dr. Beale maintains his vigorous, interesting style which has charmed so many readers in years past. His opening remarks concerning the therapeutic use of acids and alkalies in the treatment of urinary disorders contain much timely advice. The division of the work relating to urinary deposits is complete, and contains all those facts which every-day work calls to the notice of the practitioner. A full discussion of the various theories of albuminuria is given, and a *résumé* of the treatment of kidney diseases in general. The chapter on diabetes is particularly interesting. Full directions about diet in the latter malady are inserted. Dr. Beale suggests that toasted bread may be used sparingly, as "by this process much of the starch is converted into matters which do not yield sugar when acted upon by the saliva or pancreatic fluid." He does not regard all cases of diabetic coma as due to the presence of acetone in the blood. The book will be a valuable addition to any library.

Diagnosis and Surgical Treatment of Abdominal Tumors. By Sir Spencer Wells, Bart. 12mo, pp. 216. Philadelphia: P. Blakiston, Son & Co. 1885.

This book is an embodiment of the latest ideas of the English ovariotomist. It is in many respects a new work, as its scope is wider than that of any previous works of the author. He has condensed his former writings and added thereto and given us a manual within the reach of every student of surgery. Part I. is on ovarian and allied tumors. Part II. treats of uterine and other abdominal tumors, and is brought down to the present time. It contains allusions to all that is authentic concerning the surgery of the liver, kidney, spleen, omentum, gall-bladder, stomach, and intestine. In the first part an interesting chapter is given on the subsequent history of patients who recovered from ovariotomy, as obtained from the patients themselves in reply to circulars sent them. Sir Spencer Wells is evidently watching with great interest the progress of the operative treatment of peritonitis, though he does not in this volume very fully discuss the subject. It is hardly necessary to add that his style has lost none of its clearness, and that his statements are as frank as ever. From the outset of his career he has never wavered from his original determination to give the whole truth concerning his cases of abdominal surgery. The result of this conscientiousness is seen in the commanding position he now occupies, and in the valuable records his works of the last quarter century contain. No better volume than the present could serve as an introduction to a comprehensive study of the broad subject of abdominal surgery.

An Ingenious Expedient.—Recently I was called to examine a woman who has had vesico-vaginal fistula for years. The sufferer has kept herself cleanly and comfortable by using in the vagina a globular pessary made of compact sponge. The fistulous opening is near the urethral outlet; and the pessary holds the false orifice so high that the urine can be retained for hours. The patient never urinates, but evacuates the bladder every three or four hours through the agency of a catheter —an instrument she has become expert in using. The expedient might possibly be adopted in some cases where an operation for closure of the rent is not practicable. I commend the ingenuity of the woman who, unaided by even a professional suggestion, has kept herself from being offensive to herself and others.—"H.," in *Eclectic Medical Journal.*

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 8, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. W. P. NORTHRUP presented, in behalf of a candidate, a specimen of *cystic kidney with dilated ureter.*

DR. WESLEY M. CARPENTER described

A NEW IMBEDDING PROCESS

in microscopical work, devised by Dr. Maurice N. Miller, of New York, and consisting in the use of bayberry tallow. For a complete description of the method, see THE MEDICAL RECORD, April 18, 1885.

DR. WACKERHAGEN presented the specimen, and reported a case of

EXSECTION OF THE UPPER THIRD OF THE TIBIA IN A CHILD

two and a half years old. Josephine R——, born in Brooklyn, of German parents, fell on the pavement in May, 1884, bruising the left knee. As the injury appeared to be slight and the pain soon disappeared, the parents gave it no further attention until a month later, when it gradually became swollen, red, and painful. Poultices were then occasionally applied, but surgical attendance was not employed until September 25th, when an opening was made just below the knee-joint, and a quantity of dark-colored blood slightly mixed with pus was discharged.

After this treatment the swelling disappeared, leaving a small opening, just below the spine of the tibia, from which a small quantity of unhealthy pus was discharged daily.

October 15th.—Dr. Wackerhagen saw the child in consultation, and upon examination with a probe, discovered two sinuses—one taking a direction obliquely upward and inward toward the internal condyle of the femur, and the other extending downward and inward. Each sinus was about an inch and a half in length.

October 19th.—An operation was performed for the removal of the diseased bone. The sinuses were both found to be superficial. The opening in the head of the tibia was then enlarged, and the cancellous structure found to be soft and easily removed with a sharp spoon. While operating in an upward direction an opening was discovered leading into the knee-joint. He then determined to remove, by subperiosteal exsection, the entire head of the bone and about one-third of the shaft, which was found to be diseased.

Upon exploration of the knee-joint he found the crucial ligaments almost entirely destroyed and the intercondyloid space filled with unhealthy granulations. These were removed with the sharp curette, and the joint thoroughly irrigated with bichloride of mercury solution—1 in 2,000—a rubber drainage-tube was introduced into the joint, and the wound packed with iodoform and bichloride gauze.

There was no inflammatory reaction, and the temperature did not go above 99° F. Since the operation the child has greatly improved in health and appearance, the bone has been reproduced from the periosteum, and she can flex the leg to an angle of forty-five degrees and can extend it as in normal condition.

Bauer's hip-joint instrument has been applied for the purpose of continued extension. The shortening is not more than half an inch.

DR. WACKERHAGEN also presented a small

SEQUESTRUM REMOVED FROM THE INNER SIDE OF THE FEMUR AT HUNTER'S CANAL.

Mr. B——, aged forty-six years, U. S., first suffered from carbuncle over left shoulder-blade, February 15, 1883. It was treated by deep incisions. On April 20, 1883, he complained of swelling of the anterior surface of the left thigh, middle third, which proved to be an abscess. This was freely laid open, thoroughly irrigated with bichloride solution—1 in 2,000—large drainage-tubes introduced, and the wound packed with antiseptic gauze. In February, 1884, Dr. Wackerhagen was called to see the patient by his family physician, and found a sinus opening on the anterior surface of thigh, about its middle, and extending in a direct line to the femoral artery. From this sinus pus was discharging in small quantity, and necrosed bone was then discovered by passing a large leaden probe.

An operation was performed February 5, 1884, by cutting down upon the probe. When the femoral vessels were reached they were held aside by retractors, and the cloaca being enlarged, several pieces of sequestra were removed. The patient recovered with a perfectly useful limb.

DR. VAN GIESON asked if any hemorrhages had occurred before the operation.

DR. WACKERHAGEN answered that hemorrhage had not occurred, although the opening was directly under the artery, and if the piece of dead bone had been discharged it would have probably penetrated the blood-vessel.

DR. VAN GIESON referred to a case in which profuse hemorrhage took place as the result of a spicule of bone penetrating the artery.

DR. L. EMMETT HOLT presented a specimen of

EXTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR,

occurring in a woman seventy-three years of age, an inmate of the Baptist Home for the Aged, on March 16th. While stepping from one chair to another in her room, she tripped and fell to the floor, striking she knew not how. She was unable to rise without assistance. The signs presented upon examination were complete disability; slight eversion of the foot; shortening, which varied somewhat at different measurements, probably one inch; swelling and tenderness, but no marks of contusion about the hip; the trochanter carried up higher than its fellow and rather more prominent; crepitus not sought on account of the pain, which was very severe on any attempt at movement. A long side splint was applied.

On the fourth day she became suddenly unconscious, and developed an incomplete right hemiplegia. She died comatose four days afterward, and exactly one week from the receipt of the injury.

At the autopsy there were found, not to dwell minutely upon the general lesions, thrombosis of the middle cerebral artery of the left side, an atheromatous condition of all the cerebral vessels, a fatty heart, and granular kidneys. All the tissues about the left hip were filled with extravasated blood for a considerable distance in all directions. There were also some recent inflammatory products. The fracture was found to be extra-capsular, impacted, and comminuted. The line of fracture corresponded quite closely with the classical cases. It extended from the anterior superior border of the trochanter major to the base of the trochanter minor, following the anterior intertrochanteric line. Posteriorly it corresponded roughly with the posterior intertrochanteric line, the lines of fracture uniting just above the trochanter minor. The lower fragment was slightly rotated outward upon the upper, which was impacted into it. The greater part of the trochanter major was broken off as a third fragment. The bone tissue showed only moderately the usual changes found at that period of life, but the angle at which the neck joined the shaft was found by measurement, on restoring the fragments to their normal relations, to be 120°.

The comminuted character of the fracture, and especially the fact that the trochanter major was broken off, rendered it more than likely that the patient had fallen upon the trochanter when the injury was sustained.

The explanation of the rather unusual symptom of an abnormal prominence of the trochanter was apparent on examination of the specimen. The lower part of the neck was deeply impacted into the shaft, while its upper part was only slightly impacted. When removed from the body the angle of the neck with the shaft a little less than 110°.

It is an interesting question whether the unusual angle of 120° in an old lady had anything to do in causing an extra-capsular rather than an intra-capsular fracture.

THE PRESIDENT thought it important to examine the femur on both sides in such cases, and alluded to a case already reported to the Society, that of a supposed intra-capsular fracture of the femur, in which the specimen was obtained several years after the receipt of the injury and recovery of the patient, and it presented no small amount of evidence of fracture within the capsule; but on showing it to Dr. Frank H. Hamilton, he said that it could not be admitted as proof of bony union, because the other femur was not present with which the specimen could be compared, and that the deformity might be due to the partial change in the angle of the shaft with the neck, the result of senile atrophy.

DR. R. E. VAN GIESON presented a section of the skull with several fragments of bone, the result of

A GUN-SHOT WOUND OF THE HEAD.

Mary W——, thirty-nine years of age, a widow, was admitted to St. Catherine's Hospital, Brooklyn, February 21, 1884. The patient, while delirious after an attack of typho-malarial fever, went to the cemetery where her husband was buried and shot herself twice, with a pistol of 32-calibre, near the junction of the frontal with the parietal bone on the left side of the head.

When admitted to the hospital, two wounds of the soft parts in the region mentioned were found, about one and a half inch apart; apparently a wound of entrance and exit.

On using the probe a bullet was found between the openings mentioned, imbedded in the bone. Both tables of the skull at this point were fractured and depressed; there was a small slit-like opening in the dura mater, and subsequently a hernia cerebri formed. About two months after the receipt of the injury, exfoliations of bone took place (accompany specimen), and these continued until September, 1884, when the wound was entirely healed. From this time on, the patient had frequent attacks of pain, starting from the point of injury, and running to the back of the neck. But this did not prevent her from doing her work about the wards. She was also queer at times, and very stubborn. Three weeks before death she took to her bed with acute rheumatism, and developing pericarditis, died March 19, 1885, at 3½ A.M. Autopsy same day at 11 A.M.

Body.—Well nourished, slight rigor mortis.

Head.—Meninges are thickened, congested, and there is new connective tissue at the site of the wound. In the left anterior lobe there is adhesion of brain to the dura, and the dura to the pericranium. Around this, which is the site of the gun-shot wound, the brain is in a state of yellow softening. At the junction of the frontal and parietal, on the left side, is a round hole through the skull with rounded edges, just above and to the inner side of the hole are five pieces of lead, two of which are imbedded in the bone.

Lungs.—Few old adhesions at right apex.

Heart.—Soft, recent pericardial adhesions, wall of ventricle white, and fatty throughout the entire thickness, one or two vegetations on the mitral valve.

Liver and spleen.—Normal.

Kidneys.—Markings indistinct.

Uterus.—Retroflected, and firmly bound by adhesions, ovaries adherent to pelvic wall.

Dr. Van Gieson remarked that there was a negative point of interest in the case, namely, the woman was left-handed and the injury inflicted was close to the centre of speech, and yet there were symptoms of aphasia throughout the entire case.

Dr. Van Gieson also presented

A LEG REMOVED BY AMPUTATION FOR DRY GANGRENE,

in which he had been specially interested in ascertaining, if possible, the seat of obstruction in the arteries.

Franz H——, twenty-nine years of age, a native of Bohemia, and by occupation a brewer, was admitted to his service in St. Catherine's Hospital, February 25, 1885, with the following history:

About six o'clock in the morning, while loading the elevator with half-barrels of beer, one of two barrels which had been placed on the same hook, was thrown off by a sudden jerk of the chain and struck the patient on the head and chest, knocking him to the floor; the barrel then rolled over his left leg. It was found that the patient had received the following injuries: A contusion over the left eyebrow, a loss of incisor teeth, lacerated wound of lip, fracture of a rib on the right side, and a complete forward dislocation of the left knee-joint. The condyles of the femur projected into the calf of the leg, arresting circulation and producing paralysis. The tibia was found forward, its head and the patella making a marked prominence, and just above the head of the tibia and the patella was a very deep depression. The quadriceps extensor muscles were very lax, and the tendon could be easily grasped and moved from side to side. The leg was shortened about one and a half inch, and the foot turned inward. One hour after injury the dislocation was reduced by the house surgeon. The patient being under ether, the thigh was partially flexed, extension made on the ankle, and by manipulation the bones were brought in proper relations to each other.

It was noticed after reduction, that with the leg extended, and the knee as a fixed point, the leg could be abducted, adducted, and flexed forward, showing the extensive laceration the ligaments had sustained.

Posterior and lateral splints were adjusted, and ice bags applied to the knee.

February 26th.—Circulation is still poor in the foot of the injured leg.

March 2d.—Foot looks blue, feels cold, the toes are shrivelled; there is loss of sensation below the ankle. Ordered hot applications to the foot.

March 22d.—Dry gangrene of the foot is complete, with line of demarcation above the malleoli.

March 30th.—The leg was amputated by Dr. Hesse, Visiting Surgeon, at the knee-joint, with the long anterior and short posterior flaps.

There was an abscess just below the popliteal space, surrounded by baggy tissue at the time of the amputation.

Dr. Van Gieson had injected the limb with a ten per cent. solution of gelatin colored with fuchsin, which entered the vessels well, and it seemed that the anterior tibial artery was the one mainly affected, but he did not succeed in finding the exact location of the obstruction.

Another interesting point in the case, one which was raised at the consultation, was concerning the propriety of amputation at the knee-joint.

THE PRESIDENT suspected, on account of the very free lateral motion at the ankle-joint, that it also had been injured.

DR. H. J. BOLDT presented the trachea and larynx removed from the body of a man fifty-five years of age, who had suffered from

CHRONIC LARYNGITIS

for twelve or fifteen years, and about three months ago signs of pulmonary tuberculosis developed.

The question of interest was whether the laryngitis was primary or secondary, and the specimen was referred to the Committee on Microscopy.

INTUSSUSCEPTION.

DR. J. LEWIS SMITH presented a specimen showing intussusception, with the following history: Y——,

male, aged six months, bottle-fed since the age of a few weeks, has been fretful, and has had frequent attacks of colic and indigestion, as long as he has been artificially fed. On the afternoon of March 28th, he began to vomit, and to suffer more than usual from pain, which occurred in frequent paroxysms. In the intervals he was apparently comfortable and without suffering. During the subsequent night he slept little, in consequence of the pain and vomiting, and on the following morning I first visited him. His surface at this time was cool, and he was apparently without fever. He took his food readily from the nursing bottle with apparent relish, but most of it was soon after rejected. In the intervals between the attacks of pain he was quiet, and without symptoms to indicate the severe disease which was present. As he had been an habitual sufferer from indigestion, I did not at first suspect intussusception; but as the pains seemed to me to be too severe for ordinary colic, I returned in a few hours for a more thorough examination. I was informed that, during my absence, the infant had passed a few drops of blood, without fæces, and that the vomiting and pain had not abated. This excited my suspicion of an intussusception. A large clyster of tepid water was now used. This was returned, with a considerable quantity of blood and small blood-clots, and with only two small fecal masses, which had probably, from the beginning of the intussusception, lain below the invaginated part. No tumor could be felt in the abdominal cavity.

Twenty-four hours had elapsed since the displacement had occurred; there was no marked distention or tenderness of the abdomen, and apparently no fever. Immediately the treatment was commenced which, in my hands, has been most successful. The nates were raised nearly to a perpendicular above the shoulders, the rectal-tube for the adult introduced, the anus pressed firmly against the tube, and as much tepid water as possible injected. The amount retained could not be estimated, as a considerable portion of it was forced back by the efforts of the infant. When the abdomen was distended by the water, it was firmly kneaded, the fingers following the course of the colon, so as to aid in pressing back the invaginated gut, the displacement being always from above downward. During the operation, and immediately after, the sufferer always seemed somewhat relieved, but the symptoms soon after returned. The enemata and the kneading were repeated at intervals, but the displacement remained. On the following day the temperature was 100⅘°F., the abdomen was not notably distended, the loss of flesh and strength was not great, and I proposed laparotomy as the only means of saving life. Consent was not obtained until the following day, the 31st, when Dr. Sands, who saved the life of an infant of the same age by the operation, saw the case with me. As the pulse was 146, the temperature, 103½°, the abdomen considerably distended, as if from peritonitis, which, however, had not occurred, and no tumor had been, and none could be, detected, it was thought expedient not to perform laparotomy. On the following night the infant died.

Autopsy.—Abdomen much distended from fecal matter above the intussusception, and water below it; no peritonitis; the invaginated mass lay in the site of the first half of the transverse colon, against the under surface of the liver, and deeply located. Its length was about three inches, and the appendix vermiformis and the ileum protruded from its lower end. The ileum occupied the site of the ascending colon.

Remarks.—With few exceptions intussusception begins with prolapse of the ileum through the ileo-cæcal orifice, so that is is surrounded and grasped by the valve, or with the inversion of the caput coli, which becoming invaginated in the ascending colon draws after it the ileum. Hence the caput coli and the terminal portion of the ileum are the incarcerated part, and the ascending colon is the external or incarcerating portion. All the parts engaged in an intussusception may pertain to the colon, as in the specimen which I presented to the Pathological Society in 1882, which was removed from the body of a child who had suffered from the displacement several weeks, and had had the tumor in the left side of the abdomen, which was pervious so as to allow daily fecal evacuations. The displacement may also occur in the course of the small intestine, but such instances are so rare that, when called to a case, we may safely assume that we are to treat an intussusception which has commenced in one of the two ways stated above.

During the last two years I have treated successfully by water enemata, employed in the manner mentioned above, three cases of what I diagnosticated intussusception, basing the diagnosis on the presence of constipation, severe pains, vomiting, bloody stools in two of the patients, and an evident tumor in one of them. It is very important for success that the physician should be called early, make a correct diagnosis, and employ the enemata perseveringly during the first day, unless the symptoms indicate that the disease is removed. Unfortunately, as I have had opportunities to observe, the patient is often treated for dysentery on account of the bloody stools, until the displacement is too great to be remedied. Purgatives, as castor-oil, given to obviate the constipation increase the intussusception. Early diagnosis and early and correct treatment by the water enemata will, I believe, cure a large proportion of cases. Professor Sands, when inspecting the specimen in the present case, made the remark that we nearly succeeded in the reduction. Probably success might have been achieved by treatment commenced twelve hours earlier.

Formerly I have employed inflation by carbonic acid gas, which can be used by inverting a siphon of carbonic acid water and attaching the tube to the arm of the bottle. I have also employed air introduced by the bulb, especially the double bulb which accompanies the ordinary atomizer, but my preference is decidedly in favor of treatment by water. In one instance I think that the air ruptured the gut, but the child had been some days sick.

The impossibility of detecting the tumor in certain cases, and the fact that it does not remain where it formed, but passes along by the tenesmus in the course of the colon, drawing after it the ileum, as shown by this case, are noteworthy particulars.

Dr. W. P. Northrup remarked that treatment of intussusception by means of enemas of water seemed to be the best method that could be adopted. He had been interested in seeing how readily intussuceptions found at autopsy unravelled when the rectum was attached to the hose-pipe and a moderate stream of water allowed to enter. He believed that the method of treatment by injections of water was the best that could be employed, short of an operation.

Dr. L. E. Holt referred to cases reported in the *British Medical Journal*, in which the gut had been ruptured by distention with gas and water, and the writer took the ground that when these measures did not succeed within forty-eight hours, laparotomy should be performed at once, before inflammation and adhesions had taken place.

Dr. Smith thought the condition of the gut showed that an operation on Tuesday would have been proper in his case; but of course they did not know for certainty, at that time, what the exact condition was.

Dr. Holt said, the point which he wished to make was, that changes in the gut as the result of the strangulation were liable to be so great that the operation, if performed at all, should not be delayed.

The President remarked that it had been his custom not to wait longer than twelve to twenty hours, even if the diagnosis was somewhat doubtful, before making an exploratory incision at least, which, if antiseptically performed, was not specially dangerous.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. L. Waldstein reported that the specimen of supposed *congenital umbilical hernia*, presented in behalf of a candidate at the last stated meeting, was found to be as was supposed, and that it had one point of interest, namely, there was an adhesion which extended from the cœcum to the inner side of the peritoneal covering of the sac, and not in the direction of the umbilical cord. Congenital umbilical hernia was of two kinds, (1) that which occurred in the neighborhood of the umbilicus, and (2) that due to persistence of the omphalo-mesenteric ligament or duct, which cause in this case could be excluded.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 18, 1885.

A. Jacobi, M.D., President, in the Chair.

Dr. H. W. Mitchell read a paper entitled

OBSERVATIONS ON THE OPERATION FOR LACERATED PERINEUM, WITH DEMONSTRATIONS AND CASES.

The author of the paper regards the perineum as a wedge-shaped body interposed between the rectum and the vagina. The common sequelæ of laceration of the perineum were rectocele and cystocele, one or both. He had seen only partial closure of a laceration as the result simply of placing the woman's limbs in a proper position, and therefore regarded it as proper, when the parts are torn, to restore them as nearly as possible to their original integrity, which can be accomplished only by an operation, that may be one so simple it can be performed by any one possessing ordinary surgical skill and having an ordinary anatomical knowledge of the parts involved. Introduce the left fore-finger into the rectum—the laceration being separated widely by two assistants—trim off the ragged edges; denude the mucous membrane, with a pair of ordinary curved scissors, down to the median line and up as high as may seem desirable; approximate the denuded surfaces; introduce deep silver-wire sutures and superficial sutures; gather the twisted ends of the sutures in a bundle and wrap them with cloth; draw the urine with a catheter, and the operation is completed.

Dr. Mitchell discards the silk loop usually used to draw the silver wire through, and threads the needle directly with the wire, and he uses curved needles. He had operated in forty cases during the last fifteen months, and in each instance union by first intention took place. No antiseptics were used, except in five cases, and then carbolized water was employed. Strict cleanliness was observed. The bowels were kept confined for six days. The histories of the forty cases were read.

Dr. Post favored keeping the bowels open daily, after operation for lacerated perineum.

Dr. M. McLean thought that the silk loop was of great advantage in introducing the sutures. He also favored the straight and discarded the curved needle. He asked why the patients did not suffer pain after Dr. Mitchell's operation, as the sutures were introduced through the skin.

Dr. Baruch favored keeping the bowels open, and objected to the curved needle. He recommended the use of the silk loop. He was pleased to know that the author of the paper was among the minority who held that the perineum was not a buttress for the support of the uterus, etc., but rather that the pelvic organs were suspended.

Dr. Mitchell, in closing the discussion, said that he could not tell why the patients did not suffer pain. They suffered from slight pain in some cases, but the operation as he had performed it had been practically painless.

Dr. Joseph A. Andrews then read a paper on

CONTAGIOUS CONJUNCTIVITIS,

in which he dealt specially with the cause, prevention, and treatment. Under the head of "causative," he referred somewhat extensively to the history of the gonococcus, and gave the history of a single case in which he inoculated the conjunctival surface with the seventh generation of pure culture, with the result of producing a typical gonorrhœal ophthalmia.

With reference to the cause of *ophthalmia in the newborn*, Dr. Andrews said there was no positive proof that normal lochia ever gave rise to conjunctival blenorrhœa.

As to *granular conjunctivitis*, he had searched in vain in the tissue for the gonococcus or cocci like it; but cocci were found in the secretion from these eyes, which was undoubtedly contagious, and the secretion was capable of carrying the disease.

Concerning the prophylaxis of ophthalmia neonatorum, it consisted in the thorough and judicious cleansing of the vagina before labor, and, after birth, the eyes of the child, with a saturated solution of boracic acid, followed by dropping one drop of a two per cent. solution of nitrate of silver into the conjunctival sac. Then followed an extended presentation of the views of numerous observers with reference to the efficiency of Crede's method, and the measures best adapted to prevent the occurrence of the disease.

The treatment of purulent conjunctivitis consisted of washing away the matter and rendering the conjunctival surface antiseptic as nearly as possible. For irrigation the best solutions were a saturated solution of boracic acid or a two per cent. solution of carbolic acid.

Dr. Andrews exhibited an instrument which he had devised to aid in this part of the treatment, namely, a form of eye-speculum, but hollow, and so arranged that a fountain-syringe could be attached to it and a stream of the solution carried in to cleanse the conjunctival sac.

When the eye has been cleansed, paint the conjunctival surface with a two per cent. solution of nitrate of silver—if very much swelling is present, with a four per cent. solution, neutralize with a solution of chloride of sodium, and then cover the conjunctiva with an antiseptic dressing consisting of vaseline and boracic acid. Apply cold by means of pledgets of lint or pieces of muslin from blocks of ice. In severe cases the cornea is in special danger, and the douche must be used frequently.

Dr. Andrews had used iodoform, quinine, and bichloride of mercury, but found that they had no advantages over the boracic acid or carbolic acid solution.

After the adjournment, which was to the first Thursday in October, Dr. Dadirrian, introduced by Dr. Post, exhibited samples of

MATZOON, OR FERMENTED COW'S MILK.

Since the earlier periods in history fermented cow's milk has been used abundantly in Armenia, Persia, Turkey, Arabia, and other Eastern countries, by all classes, and in all seasons of the year. It is made in every house, and ordinary milk is not at all used as an article of diet.

In large cities, selling fermented milk is as prominent a business as selling milk and cream in this country. It is prepared mostly by women in the country, in the evening, and carried to market early the next morning in bags and pails.

There are two kinds: one is thick, sometimes like jelly or condensed milk; the other is liquid, like buttermilk or koumiss.

These two kinds, the one or the other, according to preference, are used for the following purposes:

1. As an article of diet. It is highly nutritious. It is used as commonly with bread by children as is butter and bread here. In Asia Minor, and even in Constantinople, matzoon is put upon the table in a large dish, and is eaten with bread as a kind of dessert.

2. In the Oriental countries ice cannot be obtained regularly or abundantly; nor are sugar and lemons readily obtained, and. when found, are expensive. Nor can beer be obtained; and again, soda water has not been introduced. The farmers. therefore, use matzoon when in the field, and by workingmen generally it is used to quench thirst. Travellers carry it in a bag on horseback, and when they reach water mix it with cold water, and use it both as a drink and for eating with bread.

3. It is used as an antidote for all kinds of poisoning. There is a general belief among the people that matzoon is an antidote for every poison, and therefore, when anyone gets poisoned they do not inquire as to what the poison is, but at once administer matzoon, and this practice has been adopted with benefit for many centuries.

4. It is used as a prophylactic during every epidemic. During the severe epidemics of cholera, typhus fever, etc., in Asia Minor and Constantinople, those who used much alcoholic stimulants and ate different kinds of fruit nearly all died, while those who used matzoon chiefly as a beverage and as food nearly all escaped. Probably the matzoon acted in two ways: (1) as a nutritious, easily digested diet; (2) antiseptically, as an acid killing the micro-organisms.

5. It is used as a panacea in all acute febrile diseases. In the interior of Asia Minor, where, in the space of one hundred square miles scarcely one regular doctor can be found, sick persons are treated either by their own families or by their neighbors. When, for example, one of the family gets sick with typhoid, typhus, or scarlet fever, measles, or small-pox, etc., all kinds of other food, either solid or fluid, are at once stopped; the patient is not allowed even pure water, but from beginning to end matzoon in the liquid form is administered. In this way the patient gets nourishment, abundance of water, and also medicine.

6. It is used particularly for impaired digestion and for chest troubles.

During his three years' practice in Asia Minor, and twelve years in Constantinople, including the period of the Russo-Turkish war, Dr. Dadirrian had ample opportunity, in the government hospitals and in private practice, to test the efficacy of fermented milk in these affections.

Matzoon is more savory than koumiss, although the two do not differ entirely from each other. The specimens of matzoon exhibited were prepared in his own house, and this was the first time it had been presented to the profession. Dr. Dadirrian also prepares Leben, used in Arabia mostly, and approved of by Professor W. H. Thomson.

Tobacco and Cholera.—The Anti-Tobacco Society of France offers a prize for the best essay bearing upon the question of the liability or otherwise of smokers to contract cholera. The essays must be based upon actual facts, as the object of the Society in offering the prize is stated not to be the condemnation of tobacco in the face of facts, but to ascertain the facts as they are, although the anti-tobacconists would doubtless not be displeased to find themselves supported in their hobby by statistics. Possibly, if a healthy stomach be a safeguard against cholera, excessive smoking may dispose to the disease by disordering digestion.

A Chromatic Diagnosis of Leprosy.—In the purchase of slaves in China, it is said, great care is taken to see that they are perfectly sound, and especially that they are free from the taint of leprosy. For this reason they are usually taken on trial for a month. In examining for leprosy the slave is taken into a dark room, and a blue flame is then passed before the face. If the skin assume a greenish hue, the master is satisfied, but if there be a red reflection from the face the presence of the dread disease is suspected and the slave is returned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PROFESSOR WOOD'S LECTURES AT THE COLLEGE OF SURGEONS—THE LAST MEETING OF THE MEDICAL AND CHIRURGICAL SOCIETY—MR. SUTTON ON THE ORIGIN OF FATTY TUMORS—MR. HUTCHINSON'S CASE OF LYMPHO-SARCOMA OF THE TONGUE—THE PEEL-GROVE BURIAL-GROUND CASE—THE HOLLOWAY SANITARIUM.

London, June 13, 1885.

As Hunterian Professor of Surgery and Pathology, Mr. John Wood, F.R.S., Surgeon to Kings College Hospital, is now delivering a short course of three lectures at the College of Surgeons, on "Hernia and its Radical Cure." Mr. Wood's views may, perhaps, not be generally acquiesced in by all surgeons, but they cannot fail to, at any rate, command respect. The subject is one which Mr. Wood has made peculiarly his own, having been engaged in its study during the last twenty-four years, that being the period which has elapsed since Mr. Wood gained the Jacksonian prize, at the College of Surgeons, for an essay containing his (then new) method of operating for the radical cure of hernia. Until within the last few years this has been the operation mainly practised by English surgeons. Mr. Wood dwelt at some length, in his opening lecture, on the "Pathology and Causes of Inguinal Hernia." He remarked that while disproportionate development in the intestines and abdominal viscera may predispose to, and assist in the formation of, a rupture, the chief causes "lie in the imperfection of the structures from delayed evolution in and about the deep hernial apertures." Speaking of the omentum, the lecturer said that, if it is elongated and so formed as to easily slip into a hernial sac and keep it open, or pressing upon the deeper hernial openings, an operation for radical cure cannot really be effective unless a portion of the omentum be also removed at the same time. "Such removal of the omentum," said Mr. Wood, "I have, in my later operations, always effected when required. Any attempt at shortening of the mesentery seems so far, even in these days of daring abdominal enterprises, to be out of the scope of practical surgery."

Mr. Wood dwelt at considerable length on the anatomy and mode of formation of inguinal herniæ. A few practical remarks were made on exercise in relation to hernia. Among exercises favorable to the prevention and cure of herina he placed hanging and swinging by the hands upon a trapeze, climbing up a pole or rope-ladder with the hands, and generally "any motion or posture which stretches out the body and increases the tension of Poupart's ligament." But force applied with the legs bent on the body and the inguinal structures relaxed, is injurious, remarked Mr. Wood. Rowing, lifting heavy weights, and straining with the diaphragm were mentioned as injurious, and tricycling received his unqualified disapproval. In all these, he said, Poupart's ligament and the adjoining structures were relaxed. The transversalis muscles forced the viscera down upon the relaxed structures in the groin. causing them to give way, and thus a rupture was produced. The rectus, also, in contracting pressed backward its sheath and the conjoined tendon and so tended to open up the canal.

The Medical and Chirurgical Society closed its labors for the present session on Tuesday last. Two papers were then read. One of these was by Mr. J. B. Sutton, and was virtually a pathological essay, being an elaborate disquisition on the origin of fatty tumors. Mr. Sutton's theory is that any of the soft tissues of the body, normal or pathological, may degenerate into fat, and that, in some cases, this retrograded tissue assumes an autonomy and grows into a veritable fatty tumor. This theory Mr. Sutton elaborated with a good deal of ingenuity and

learning. He referred to cases which lent support to the notion that congenital fatty tumors containing bone are really examples of parasitic fœtuses whose soft parts have retrograded wholly or partially into fat. In the ensuing discussion Mr. Sutton remarked that a parasitic fœtus may remain attached as long as thirty years and even then move its limbs, thus showing that it is certainly a rudimentary fœtus enjoying life.

The other paper was by Mr. Hutchinson, and described very fully the history of a case in which a large lympho-sarcomatous tumor was removed from the tongue by Mr. Hutchinson. The growth began in early life in the substance of the tongue, and ultimately attained such a size as to fill the mouth. Its growth had been slow and painless. It was of stony hardness, its surface covered at one part with papillary outgrowths, but there was no tendency to ulceration. There was no gland-disease. When the patient (a medical student) was twenty-two years of age it was removed on account of its bulk, the patient being otherwise in good health. When removed it was found to weigh seven ounces, having been at least twelve years in growing. After two years immunity, a new growth suddenly developed in the scar, increased very rapidly, and caused the death of the patient.

The case of the "Peel-Grove Burial-ground," has been before the law courts again during the last few days. The plaintiff sued the defendant for rent, the land having been let for building purposes. Since the ground was let, an Act of Parliament has passed forbidding building on any disused burial-ground. On this ground the claim was resisted. I will not weary your readers with a discussion of the legal questions brought forward, but will briefly draw attention to a few points of sanitary interest. The first interment took place in 1840, and the burial-ground was closed in 1855. Its total area was less than three-fourths of an acre. The chaplain, who officiated from 1844 to 1855, gave evidence that he had officiated at the burial of 11,300 persons. The total number buried, he estimated to be between seventeen and eighteen thousand. The graves were from twenty to twenty-five feet deep. Each grave contained the bodies of ten or twelve adults and double as many children. There was no space between the coffins. The neighborhood is now densely populated. I am glad to say the judge disallowed the claim, remarking that the whole proceeding was an unholy compact.

On Monday next the Prince of Wales is to open the "Holloway" Asylum, at Virginia Water, designed for the care and treatment of the mentally afflicted of the middle classes. The institution is a handsome building of red brick and stone, and has been erected with a large legacy bequeathed for that purpose by "Professor" Holloway, of pills and ointment fame. A duly qualified medical superintendent has been appointed.

OUR PARIS LETTER.

(From our Special Correspondent.)

CALORIFICATION—TRANSPLANTING AN EYE—CHOLERA—THE TREATMENT OF PROGRESSIVE MYOPIA—DEATH OF DR. NOËL GUENEAU DE MUSSY.

PARIS, June 12, 1885.

In pursuing his researches on the temperature of the human body, Dr. Charles Richet lately communicated a note to the Academy of Sciences on the influence of the nervous system on the process of "calorification," or generation of heat in the organism. His new experiments have proved that the nervous system is the regulator of animal heat, it is more by an action on chemical life than by an influence of the vasomotor system. In fever one loses more heat than in the normal condition; in the state of algidity one loses less heat than in the normal, so that the temperature, in these two conditions is in constant relation with the production of heat. Hence the changes in the production of heat, at least in animals provided with a thick fur, have more importance in determining the general temperature of the body than the changes caused by loss of heat.

The operation of skin-grafting was justly considered a great achievement in surgery, but up till now the grafting of entire organs, except perhaps teeth, and that with those of animals completely dissimilar in their nature has not to my knowledge been heard of. Dr. Chibret, of Clermont-Ferrand, lately astonished the Paris Academy of Medicine with a note, announcing that he had replaced the eye of a young girl, which he had to remove to prevent sympathetic ophthalmia of the other, with that of a rabbit. A fortnight after the operation, when Dr. Chibret forwarded his communication, matters seem to have been in the most satisfactory condition, that is as far as the fixing of the eye is concerned, but no mention is made as to whether the patient can see with the eye or not. But for the high standing of the author in the profession, who is a distinguished ophthalmologist, the whole affair might have been considered a joke, but as he promised to give full details of the case at an early opportunity, we must suspend further comments on the subject.

After having ascertained that the epidemic now raging in the province of Valencia is the genuine Asiatic cholera, and after having hesitated to put into practice Dr. Ferrán's method of cholerization, the Spanish Government has organized a special commission to report on it, after having personally observed the effects of the inoculations practised by Dr. Ferrán with the microbes cultivated from the dejections of choleraic patients. The experiments were to be performed on persons and animals. Children were to be inoculated with the consent of their parents, whilst adults were to receive instructions direct from Dr. Ferrán. The persons inoculated were to be taken from divers classes of society, and the report of the Commission is to be forwarded to the Faculty of Medicine of Madrid for its opinion and for ultimate publication.

The report of the outbreak of cholera at Marseilles has been officially contradicted. Nevertheless, every precautionary measure is being taken to prevent an incursion of the plague.

In a memoir addressed by Dr. Dransart to the Academy of Sciences on the treatment of progressive myopia by iridectomy and sclerotomy, the author, supported by numerous observations, considers that, as these operations have effected a revolution in the treatment of glaucomatous affections, the same operations would be still more efficacious to combat progressive myopia, which in his opinion contributes largely to the number of cases of blindness noticed each year. The following are the conclusions of the memoir: 1, the circulatory theory which explains the production of glaucoma is also that which explains the genesis of myopia; 2, it is expedient to practise sclerotomy or iridectomy in the cases of progressive myopia, in which the visual acuity is reduced to one-fourth, and even to less, and in which the progress of the malady had not been arrested by the ordinary therapeutic means; 3, these operations arrest the progress of the disease, maintain visual acuity, which may be even doubled, or even restored, in certain cases, when it has disappeared altogether, either qualitatively or quantitatively; 4, iridectomy should be almost always performed as a preventive of detachment of the retina, and in this way suppress the principal factor of cecity by myopia.

At the meeting of the Academy of Medicine last week the President announced the death of Dr. Noël Gueneau de Mussy, which had just taken place, and to which he referred in the most touching terms. By this death the medical profession of Paris has lost one of its most eminent members. Gueneau de Mussy was born on November 6, 1813, and was the grandson of the celebrated Professor Hallé. Besides being a distinguished physician, he was a man of letters. After having taken his degree in 1839 he was chosen by Chomal as his Chef de Clinique. In 1847 he was promoted to Ayrégé, and in

1867 he was elected member of the Academy of Medicine. He was for a long time Physician to the Hôtel Dieu, which post he held till within a few years ago, when he was obliged to retire, owing to his having reached the limit of age (sixty-six) allotted to hospital physicians. He was, however, retained as consulting physician, and his vast experience and great diagnostic powers were taken advantage of whenever opportunity offered. He was well versed in the English language, which enabled him to introduce into French medical literature the theories and experience of the great English and American authors. He had just completed the fourth volume of his "Clinique Médicale," which treats of cases observed by him in his hospital and private practice. The third volume of this work was devoted exclusively to typhoid fever, and may be considered almost a reproduction of the works of Dr. Murchison and of other British authors on the subject, at least in so far as is concerned the etiology of the disease.

ON RUPTURE OF THE PERINEUM.[1]

To The Editor of The Medical Record.

Sir: Will you please publish in The Record my supplementary remarks on Rupture of the Perineum, made after the reading of the paper. They were substantially as follows:

Gentlemen: As I cannot remain until the discussion of the several papers to be read this evening is closed, the President has permitted me to make a few supplementary remarks.

Speaking of the means to be employed to prevent a rupture of the perineum, Dr. Barker, in his excellent treatise on "Puerperal Diseases," says that, to avert this accident, he has often, near the close of labor, pushed the chloroform to the production of *profound* anæsthesia, with the result of relaxing the muscular fibres of the perineum and without delaying the progress of labor.

I regard this as an error in theory and of observation. I do not think the muscular fibres of the sphincter vaginæ ever offer any resistance to the advance of the head at this stage of labor. They have been stretched beyond their normal length four or five times at least, and in this condition they must have lost all contractile power. Certainly, while the distending force is continued no degree of anæsthesia could cause these fibres to relax. It might diminish the force of the uterine contraction and thus relieve the perineum, but when the contractions returned the perineum would be subjected again to the same strain. Dr. Barker intimates, however, that the uterine contractions are under these circumstances in no way affected. To my mind his theory is incredible, and his observations are therefore erroneous.

I wish further to call your attention to some remarks of Dr. Meigs, the late Professor of Midwifery in the Jefferson Medical College, Philadelphia, who enjoyed a very large obstetrical practice for many years, which will show how seldom in his personal experience a perineal rent demanding operative interference occurred. "I defy," he says, "any one to point out the sample of a female who has suffered under any durable lesion, etc., who has been attended by me." He objects also to the primary operation as worse than useless.

Such testimony as this as to a matter of fact—and it corresponds with my own personal experience—cannot properly be ignored, no matter how old the testimony may be.

And last, I wish to call your attention to the letter of the Vienna correspondent of The Medical Record. In the number of that journal for June 13, 1885, he states that in the Vienna Obstetrical Hospital there are confined every year about nine thousand patients. The building has been used for this purpose the last hundred years. Antiseptic precautions are enjoined, but some of the most important precautions do not receive practically the slightest attention. During the three months preceding his report seven hundred women were delivered, and only three died, one of which number was a Cæsarean section, and this was the only septic case. The average mortality of the hospital is placed at less than one-half of one per cent.

Speaking of the general management of labor in this hospital, the writer says: "The entire absence of medicine to hasten the labor when too slow, or relieve severe pains, or to induce them when wanting or feeble, is noticeable. Avoidance of *any kind of interference* in labor is carried to the greatest extreme. Even for forceps operation or a version, unless extremely difficult, no anæsthetic is administered. Great care is taken also to prevent the least injury to the os uteri. The utmost respect is paid during labor to this part. It must dilate normally and in its own time. Artificial dilatation is not permitted, even with the finger, and all mechanical appliances for dilatation are 'inventions of the devil.' The placenta is usually expelled by Crede's method."

"Rupture of the perineum in onecase in a hundred of primiparæ is a rarity;" but when it does occur it is at once closed by silk sutures. Upon this latter point alone my opinions are not in accordance with the opinions and practice of the Vienna surgeons, and this is a point of relatively small importance.

Frank H. Hamilton, M.D.

[1] Supplement to Dr. F. H. Hamilton's paper, read before the New York County Medical Association, June 15, 1885, and published in this Journal, June 20, 1885.

MEDICAL MANNERS.

To the Editor of The Medical Record.

Sir: Your ingenious fellow-countryman, Mark Twain, tells us, in a foot-note to his "Answers to Correspondents," that the advice given to the "Young Poet" was taken *au grand sérieux* by the *Saturday Review*, which seized the occasion to hold up to British scorn the invincible ignorance of American editors. We have all been rather pleased to think that the omniscient *Saturday Review* should have been caught tripping, but it seems that what is very obviously a joke on this side of the Atlantic may be regarded as solid material for a serious article in the New York Medical Record, and may actually afford a basis for congratulation "to the profession in this country" (*i.e.* America) that you are "not so dependent upon manners" as your brethren in England.

I can assure you that the letter from a practitioner of "fifty-one years' standing" was undoubtedly a *jeu d'esprit*. Another time he ought to be careful and write himself a practitioner of "a hundred and fifty-one years' standing," and then there would be no mistake of this kind. You evidently have not noticed that the *Medical Times* has been making vigorous efforts to take rank as a serio-comic paper. Its efforts so far have been heavy, but they are none the less exceedingly well meant.

Manners here, as elsewhere, are based mainly on good sense and good taste, self-control, self-respect, and respect for other people. These are qualities which I hope are cultivated and regarded with equal favor on both sides of the Atlantic, as they certainly form a most important element of success in the stock in trade of any young physician.

I am, yours obediently,

Robert Saundby, M.D.

Birmingham, Eng., March 4, 1885.

Infant Mortality in Russia.—More than sixty per cent. of the children in Russia die under the age of five years, about two millions of them perishing every year. Not one-half of the males attain to the age of thirty-five, and one-third of those who survive this age are incapacitated for military service by reason of their low stature or of constitutional debility.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 21, 1885, to June 27, 1885.

HARTSUFF, ALBERT, Major and Surgeon. Assigned to duty at Fort Hamilton, N. Y. H. S. O. 133, Department of the East, June 24, 1885.

MIDDLETON, J. V. D., Major and Surgeon. Granted one month's leave, with permission to apply for fifteen days' extension; to take effect about 15th prox. S. O. 88, Department of the Missouri, June 19, 1885.

BROWN, H. E., Major and Surgeon. Assigned to duty as Post Surgeon, Fort Reno, Ind. T. S. O. 91, Department of the Missouri, June 24, 1885.

TAYLOR, BLAIR D., Captain and Assistant Surgeon. Ordered from Department of Texas to Department of the East. S. O. 141, A. G. O., June 20, 1885.

CARTER, WILLIAM F., Captain and Assistant Surgeon. Ordered from Department of the East to Department of Texas. S. O. 141, A. G. O., June 20, 1885.

DAVIS, WILLIAM B., Captain and Assistant Surgeon. Leave of absence extended three months. S. O. 142, A. G. O., June 23, 1885.

EBERT, R. G., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect about July 5. S. O. 97, Department of Colorado, June 17, 1885.

ROBERTSON, R. L., First Lieutenant and Assistant Surgeon, now on leave of absence, directed to report in person by July 7, 1885, to Commanding Officer of Columbus Barracks, Ohio, to accompany detachment of recruits to Department of Texas. On completion of this duty to rejoin his proper station. S. O. 143, A. G. O., June 24, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 27, 1885:

June 27, 1885	0	3	9	1	21	34	0	0

THE HEALTH OF BARCELONA.—We have received from Señor Bolibar, the editor of *Industria e Invenciones*, a pamphlet of nearly one hundred pages, treating of the sanitary condition of Barcelona, and of the means necessary to improve it. The author, Señor García Fària, is thoroughly impressed with the necessity of instituting sanitary reforms in his native city, and has performed his laborious task with a zeal worthy of his object. The work is accompanied with thirty-seven statistical tables, showing the comparative death-rates in all the principal cities of Europe and America, their mean temperature, their elevation above the sea, their sanitary condition, etc., compiled with great care from official sources. The necessity of the work is shown by the fact that the death-rate of Barcelona is 32.5 per one thousand, while that of London is but 19. Over fifty per cent. of the deaths are of persons under thirty years of age, and forty per cent. are from infectious diseases. This high death-rate is not chargeable to the unfavorable situation of Barcelona, but, as the author points out, to insufficient sewerage, poor water-supply, and defective pavements. On account of its tables this monograph will be very serviceable to many who take no particular interest in the sanitation of Barcelona apart from that of other cities.

VASELINE IN PASTRY.—A French sanitary committee has recently reported adversely against the practice of certain bakers of using vaseline instead of butter in pastry. The chairman in his report said that cakes made with vaseline did not become sour, but that this was a disadvantage for the consumer, as he was thus more liable to be deceived as to the freshness of his purchases. Vaseline furthermore was deficient in the nutritive properties possessed by butter and lard, and data were wanting to prove that it was not even injurious to the organism.

A NEW BRAZILIAN JOURNAL.—The first number has appeared of the *Revista dos Cursos Praticose Theoricos da Faculdade do Medicina do Rio de Janeiro.* The editors are Drs. Cypriano de Freitas, Hilario de Gonvêa, Erico Coelho, Martin Costa, and Lima e Castro. It is the official organ of the medical faculty of Rio de Janeiro, and, as it is published at the expense of the government, it may well anticipate a life as long as its name. And, indeed, if the subsequent numbers equal in excellence the first, the longevity which we wish it will be deserved.

THE SUGAR OF THE BLOOD.—According to Dr. J. Seegen (*Annales de la Société Médico-Chirurgicale de Liège*) the sugar contained in the blood is glucose. It is found in large quanties in the liver, and is decomposed in the organism, but it is only slightly, if at all, diminished in amount in its passage through the lungs. The blood of the carotid artery contains about the same proportion as does that of the right ventricle, but the blood of the hepatic veins is charged with double the quantity that is found in the portal vein. The total mass of the blood in dogs contains from one to one and a half parts per thousand of glucose.

A NOVEL THEORY CONCERNING THE PREVENTION OF CHOLERA.—Lyons is said to have hitherto enjoyed a singular immunity from cholera. Numerous theories have been advanced to account for this, but certainly one of the most original, if not the most satisfactory, was that invented many years ago by M. Levicaire, of Toulon, and recalled by the *Lyon Médical* of a recent date. This eminent physician regarded cholera as a poisoning by hydrocyanic acid. The alleys in Lyons, it seems, are used by the male population as public urinals, much as they were formerly in Cincinnati and other of our Western cities. "And it is precisely because every one makes water in the alleys that Lyons enjoys a freedom from cholera, for the ammonia so produced neutralizes the hydrocyanic acid," said M. Levicaire.

ANCIENT DENTISTRY.—In the museum of Cometo, in Tuscany, von Marter recently discovered a skull containing false teeth. They seemed to have been made from the teeth of animals, and were fastened to their natural neighbors by means of narrow gold bands. The tomb from which this skull was taken, was said to date back to the fifth or sixth century before the Christian era.

ADONIDIN.—This substance is a glucoside derived from the adonis vernalis, a plant of the family of ranunculaceæ. It increases arterial tension, regulates the action of the heart, and augments the renal secretion. It is administered in daily doses of one-thirteenth to one-ninth of a grain, gradually increased to one-third or one-half a grain. It is said to possess a cumulative action and its administration should therefore be suspended every fourth or sixth day.

The Medical Record

CASE OF .
POISONING RESULTING FROM CHLOROFORM TAKEN INTERNALLY—RECOVERY.

SUPPLEMENTED WITH A TABLE OF REPORTED CASES.

By LLEWELLYN ELIOT, M.D.,

ATTENDING PHYSICIAN TO ST. ANN'S INFANT ASYLUM, CENTRAL DISPENSARY, EMERGENCY HOSPITAL, ETC., WASHINGTON, D. C.

REPORTS of cases of poisoning following the internal administration of chloroform are scattered through the literature of medicine. To collect these various reports and to show their treatment is the object of this paper. When summoned to the case which is recorded below, I was struck with the absence of information regarding treatment in text-books upon materia medica, therapeutics, and toxicology. The table accompanying is the result of an investigation into this subject, extending through two years: it shows upon its face the picture of each case, but for the use of those who may desire to extend this investigation beyond its present limits, as well as for the purposes of general information, the record of each case is appended in abstracts.

Glancing at our table we find death resulted in 16 cases; of this number but 6 died in twenty-four hours, the other 10 surviving varying periods until the eighth day. A fatal issue results from the intensity of the œsophageal, tracheal, and gastric symptoms. One case (No. 15) should properly be excluded from consideration, as it is surrounded by such an element of doubt; this would give a mortality of 15 in 56 cases, or 26.78 per cent.

Chloroformum, methenyl chloride, terchloride of formyl, according to Wood, was discovered by Mr. Samuel Guthrie, of Sackett's Harbor, N. Y., in 1831. It results from the action of bleaching powder (chloride of lime) upon methyl or ethyl alcohols, or of chlorine upon marsh gas. It is a heavy, colorless fluid, practically uninflammable, but will burn with a greenish flame; its smell is powerful and agreeable; taste hot, sweetish, and aromatic; solvent powers extensive; specific gravity 1.525 at zero and boils at 62° C. (143.6° F.); insoluble in water, soluble in alcohol and ether; unaffected by concentrated sulphuric acid. There are two officinal forms—chloroformum venale and chloroformum purificatum.

Chloroform is introduced into the system through the lungs, the stomach, and the skin. Whether its action depends upon an altered condition of the blood or upon its direct action upon the nerves is not certain; it is more than probable that both theories are correct—upon the blood by increasing its carbon and rendering it thicker, and upon the nerves by its paralyzing effect. That it acts upon the blood by destroying its red disks in the body is proven by the appearance of icterus following its administration either by inhalation or by the mouth (L. Hermann: *Archiv für Anatomie, Physiologie, etc.*, 1866).

Chloroform from its quickness of action and smallness of dose is superior for surgical and obstetrical purposes to any other anæsthetic, although it has an increased amount of danger over ether, nitrous oxide, and bromide of ethyl. Its mortality is 1 to 5,860, that of ether 1 to 16,542, that of nitrous oxide 1 to 100,000. It is not an agent to be used indiscriminately nor in the absence of proper antidotes.

Deaths are rather due to paralysis of the heart and respiratory organs. When administered internally the symptoms produced are of the same character only more intensified and more lasting than those following inhalation. A stage of transient excitement, most marked in athletes and drunkards, muscular relaxation, abolition of sensibility and consciousness, profound narcosis, stertorous breathing and abolition of reflex actions are the essential symptoms following the administration of this drug either by inhalation or by the mouth. Although rarely prescribed internally it is sometimes useful in neuralgia, colica pictonum, delirium tremens, renal calculi, ague, and to relieve the pain and vomiting of cancer of the stomach. Chloroform is administered under but three conditions, namely: first, by surgeons for surgical purposes; second, by medical men and others to induce sleep, obtain relief from pain, or for suicidal purposes, and third, for its intoxicating effects. A few cases have occurred where it has been taken by mistake for some other fluid. I have never seen its successful administration to sleeping subjects, although I have experimented upon them.

It is impossible to state with exactness the amount of chloroform that can be administered by inhalation; the concentration of the vapor and the length of time during which it is used are to be considered. In a successful case of puerperal eclampsia where I assisted there was one pound and a half administered during thirty-six hours. The same holds good in regard to the fatal dose taken by the mouth. Recorded cases show quantities varying from half a drachm to six ounces. The indications of the administration of a fatal dose, in addition to general muscular relaxation, perfect anæsthesia, and insensibility, are cyanosis, convulsions, jaundice, sudden paleness of the face and lips, stoppage of the pulse and respiration, involuntary passage of urine and fæces. In treating cases of narcosis following internal administration, the first indications are to evacuate the stomach by an emetic, or preferably by the stomach-pump. The stomach may be washed out and the restorative remedies introduced. Fresh air, sinapisms, flagellations, cold douche, strong coffee, with ammonia, strychnia, digitalin, or morphia sulphate hypodermically administered are the measures to be adopted; at the same time artificial respiration, lowering the head to the general level of the body, drawing the tongue forward, lifting the chin, application of hot irons to the skin, and the inhalations of nitrite of amyl should be employed. Electricity is advocated upon theoretical grounds. Recently subcutaneous injections of apomorphia have been suggested by Dr. Reuss (Case 41); the employment of this powerful emetic would no doubt hasten recovery if used in time, but few physicians have it always at hand. The employment of ammonia as a stimulant, in preference to alcohol, is based upon theoretical considerations, alcohol increasing the already increased amount of carbon in the blood, while ammonia acts merely as a powerful stimulant. This view was brought forward by Spence.

The post-mortem[1] appearances are not pathognomonic. The gastro-intestinal tract is reddened, ecchy-

[1] In the abstracts all post-mortem appearances not connected with the result of chloroform-poisoning are omitted.

mosed, and shows other signs of severe and intense inflammation.

The dose generally prescribed for internal administration is from fifteen drops to one drachm in mucilage, glycerine, or sweetened water.

On Sunday, January 14, 1883, about four o'clock in the evening, I was summoned to see General B——, sixty years of age, who had swallowed chloroform. Upon my arrival at the house, ten minutes after, his wife informed me that he had taken the bottle containing six ounces of Squibb's chloroform and swallowed two ounces. She had given him mustard-water and "a few drops of water of ammonia." He was lying upon the bed in an apparently exhausted condition, with sunken eyes, anxious expression, dilated pupils, coldness of the extremities, a weak pulse of 70, intense burning in throat, stomach, and over the abdomen, sighing respiration, and great inclination to sleep. He was given pulv. ipecac, zinc sulph., āā 1 gramme, to be repeated; soon violent nausea and retching set in, and the stomach was emptied of a yellowish fluid, smelling strongly of chloroform; this vomiting was repeated twice, when the fluid was streaked with blood. To combat the drowsy condition very strong coffee was given him; to allay the burning sensation plenty of sweet oil. In about two hours he was sufficiently recovered to be left with his attendants, leaving instructions to continue a systematic series of pulling and calling and administration of strong coffee. I promised to call at 8.30 the same evening, when his only discomfort was the excessive burning about the mouth and throat. The free use of sweet oil afforded relief. On the next morning he appeared very well, was ordered a gargle of chlorate of potash and slop diet. In a week he was entirely recovered.[1]

Case 1.—Adult male, aged twenty-two, took four ounces. Seen in three hours. Appeared as if intoxicated; skin below normal; pupils dilated and insensible to light; respiration tranquil; pulse 65 and small. Stomach was washed out with tepid water; then with brandy-and-water; then one gramme of compound spirits of ammonia introduced. Vomiting followed; became profoundly comatose; breathing stertorous and puffing; skin cold; pulse imperceptible; general convulsions. Placed in blankets and surrounded by warm water in tins; sinapisms to chest and large blister to nape of neck. Became sensible thirteen hours after taking the chloroform; on the fourth day he was discharged entirely cured. He stated that he lost sensibility from the time he drank the chloroform.

Case 2.—F. D. M——, aged thirty-one, took thirty grammes thirty drops. Heat and burning of air-passages, œsophagus, and stomach; in ten minutes was delirious; pupils neither dilated nor contracted, mobile; respiration unembarrassed. Given sweetened water and a few drops of aqua ammonia, without effect. Recovery. This occurred in a case of treatment of colica pictonum.

Case 3.—Wm. W——, aged twenty-seven, on December 6, 1851, took two mouthfuls. Seen in six hours. Breathing stertorous and heavy; pupils dilated; pulse 60, full and soft; total insensibility; face livid; lips almost black. Stomach washed out with warm water and mustard; turpentine over chest and abdomen, also by enema. Improvement. Death in thirty-six hours. Post-mortem examination showed congestion of mucous surface of pharynx and of the brain.

Case 4.—Male child, aged four, took from one to two drachms. Seen in thirty-five minutes. Insensibility; pupils contracted; breathing laborious; pulse quick and full; face pale; extremities cold; afterward pupils became alternately dilated and contracted; face livid and pale; pulse quick and full, then imperceptible; breathing stertorous. Treatment: Sulphate of zinc; stomach-pump; sinapisms; ammonia to nostrils; leeches; artificial respiration; then warm bath. Died in three hours. No post-mortem examination.

Case 5.—Mr. H—— was ordered for delirium tremens the following: ℞. Chloroform, ʒ v.; pulv. glycyrrhiza, ʒ j.; mist. camph., ʒ ixss. M. Sig.: One ounce dose. He took the whole at one dose. No bad effects followed; was jaundiced. Recovered. No notes in detail.

Case 6.—Female, aged twenty-one, on May 19, 1856, took two ounces. Seen in twenty minutes. Symptoms resembled opium poisoning; perfectly unconscious; pupils contracted; temperature normal; respiration tranquil and regular; pulse 78, soft and tolerably full. Treatment: Stomach-pump; sinapisms; aromatic spirits of ammonia with brandy. Respiration continued to decrease until it fell to two in the minute, and finally ceased for nearly two minutes. Galvanism; stimulating enemata every half hour. May 25th was able to sit up, and the following day returned to work.

Case 7.—Adult male, who took six ounces in the Royal Infirmary, Edinburgh, some years ago. He recovered from the immediate effects, but died in forty-eight hours of acute gastritis. Stimuli and galvanism were used. This case is related from memory, and the name of the medical attendant is not given.

Case 8.—H. P——, male, adult, on August 12, 1856, took three and a half ounces. Seen in a few minutes. Immediate symptoms of intoxication; vomiting violently and in a state of wild excitement; insensibility; hiccough; pulse frequent, weak, and jerking. Pupils varied, sometimes dilated at others contracted; breathing became slightly stertorous. Treatment: Stomach-pump; galvanism; cold affusions; shaking. Recovery from poisoning in nine hours. Slight gastritis followed.

Case 9.—C. C——, aged twenty-three, took four to five drachms. Seen in two hours. He immediately experienced burning in the throat, fauces, and epigastrium; in half an hour he vomited; breathing became slower; pupils contracted and then dilated to such an extent that scarcely any iris could be seen, and so remained until his recovery; surface became cold; pulse imperceptible; jaws firmly clenched; respiration but faintly perceived; blood and mucus exuded from mouth and nostrils. Treatment: Cold affusions, artificial respiration, and enema of turpentine. Recovered entirely in a few hours with no bad results except slight subacute gastritis.

Case 10.—Mary McN——, aged thirty-five, took an ounce and a half. Seen in twenty minutes. Insensible; stertorous breathing; pulse slow and feeble; pupils contracted. Treatment: Mustard sinapism; dry cups; frictions; stomach-pump, and brandy. Gastritis followed and she died in twenty hours. Autopsy showed softening of the mucous membrane of the stomach to such an extent that it could be scraped off in shreds.

Case 11.—Harry T——, Company F, Second Cavalry, took two ounces. Seen in ten or fifteen minutes. Had vomited; insensible; breathing stertorous; pulse about 60; respiration became very slow and feeble; pulse reduced to 40, scarcely discernible and intermittent; face purple. Treatment: Stomach washed out with a pint and a half of warm water. Spt. ammon. aromat., ʒ ij., introduced before tube was withdrawn. Cold douche; stimulating enema; sinapisms. Sensibility returned in seven hours. Slight gastritis and jaundice followed. He was returned to duty.

Case 12.—Female adult, aged twenty-two, on March 24, 1857, took nearly one ounce. Seen in five minutes. Total insensibility; pupils dilated; pulse full and oppressed; foam at the mouth. Treatment: Fresh air, brandy-and-water, stomach-pump, ammonia to nostrils, cold water dashed in the face. March 27th was up, walking about; pulse regular and equal. Subject was an epileptic.

Case 13.—Female adult took on October 27, 1858, a wineglassful. Seen four and a half hours afterward. Pupils slightly contracted; pulse 84, moderately full; breathing abdominal, without stertor; total insensibility;

[1] For assistance in collecting the cases from the German medical journals I am greatly indebted to Drs. Behrend and Kolopinski, of this city.

Table of Reported Cases of Poisoning by the Internal Administration of Chloroform.

No.	Reference.	Reporter.	Sex.	Quantity taken.	Time elapsed before seen.	Pulse.	Respiration.	Pupils.	Result.	Remarks.
1	Lond. Med. Gaz., vol. xii., p. 675, 1851.	A. S. Taylor, M.D., F.R. S.	Male, 22 yrs.	ʒ iv.	3 hours.	65, small, became imperceptible.	Tranquil, afterward became stertorous and puffing.	Dilated, insensible to light.	Recovery complete in 4 days.	
2	Bull. Gen. de Thérap., etc., Paris, vol. xlii., p. 296, 1852.	Dr. F. A. Aran.	Male, 31 yrs.	30 grs. 30 gtt.	10 minutes.	Between 72 and 80.	Without uneasiness.	Neither dilated ner contracted.	.....	This case occurred during the course of treatment of "colica pictonum.
3	Monthly Jour. Med. Sc., Lond. & Edin., vol. xiv., p. 77, 1852.	E. R. Bickersteth, Esq.	Male, 27 yrs.	Two mouthfuls.	6 hours.	60, full and soft.	Stertorous and heavy.	Dilated.	Died in 36 hours.	Autopsy.
4	Ass'n Med. Jour., Lond., vol. i., p. 354, 1834.	F. H. Hartshorne, Esq.	Male, 4 yrs.	ʒ j to ʒ ij.	35 minutes.	Quick and full, then imperceptible.	Laborious, then stertorous.	Contracted, then varied.	Died in 3 hours.	No autopsy.
5	Dublin Hosp. Gazette, vol. i.,	Dominic Corrigan, Nov. 15, 1854.	Male, adult.	ʒ ivss.	.....	.....	.....	.....	Recovery.	In a case of "delirium tremens," no bad effects.
6	Lond. Lancet, vol. ii., p. 159,	J. Spence, Esq., F.R.C.S.E. 1856.	Female, 21 yrs.	ʒ ij.	20 minutes.	78, soft and tolerably full.	Regular and tranquil, but continued to decrease until it fell to two a minute, and finally ceased for nearly two minutes.	Contracted.	Recovery complete in 7 days.	
7	Lond. Lancet, vol. ii., p. 159,	J. Spence, Esq., F.R.C.S.E. 1856.	Male, adult.	ʒ vj.	.....	.....	.....	.....	Died in 48 hours of acute gastritis.	Occurred at the Royal Infirmary, Edinburgh, cited from memory.
8	Ass'n Med. Jour., Lond., vol. ii., p. 733, 1856.	T. Holmes, Esq.	Male, adult.	ʒ iijss.	Few minutes.	Frequent, weak and jerking.	Became slightly stertorous.	Varied.	Recovery, with slight gastritis following.	
9	Virg. M. and S. J., Richmond, vol. vii., p. 369, 1856.	— Frick, M.D.	Male. 23 yrs.	ʒ iv. to ʒ v.	2 hours.	Imperceptible.	Became slower until faintly perceived.	Contracted, then very widely dilated.	Recovery in a few hours, gastritis following.	
10	Med. Exam., Phila., vol. xii.,	Junius Wdliams. p. 659, 1856.	Female, 35 yrs.	ʒ jss.	20 minutes.	Slow and feeble.	Stertorous.	Contracted.	Died in 20 hours.	
11	Am. Jour. Med. Sc., Phila., vol. xxxiv., p. 367, 1857.	C. H. Smith, A.S., U.S.A.	Male, adult.	ʒ ij.	10 to 15 minutes.	About 60, became reduced to 40, and scarcely discernible and intermittent.	Stertorous, became slow and feeble.	.....	Recovery, with slight gastritis and jaundice.	
12	Med. Times and Gazette, Lond., p. 615, 1857.	H. D. Dean, M.R.C.S.L., S.A.	Female, 22 yrs.	Nearly ʒ j.	5 minutes.	Full and oppressed,	.....	Dilated.	Recovery in 3 days.	
13	Lond. Lancet, vol. i., p. 400, 1859.	W. P. Bain, M.D.	Female, adult.	Wineglassful.	4½ hours.	84, moderately full.	Abdominal, without stertor, stopped for thirty seconds.	Slightly contracted.	Died on eighth day of acute gastritis.	Autopsy.
14	Am. Med. Times, N. Y., vol.	T. C. Finnell, M.D. ii., p. 153, 1861	Female, 18 yrs.	ʒ j.	20 minutes.	Feeble and quick.	Stertorous.	Contracted and insensible to light.	Recovery in 3 hours.	
15	Be. f. gerichtl. anthrap. Nurnberg, Bd. xii., p. 317, 1861.	.....	Male, 28 yrs.	¼ lb.	2 hours.	.....	.....	.....	Death.	This case is very doubtful.
16	Med. Times and Gazette, Lond., vol. i., p. 478, 1862.	Alex. Lamm, M.D.	Male, 35 yrs.	ʒ jss.	7 hours.	Full though slow.	Hurried and audible.	Highly dilated, and insensible.	Death in 23½ hours.	Autopsy.
17	Med. Times and Gazette, Lond., vol. i., p. 577, 1862.	H. M. D. S., M.D.	Male, 50 yrs.	ʒ ij.	7 hours.	Slow and feeble.	Movements of thorax scarcely perceptible.	Widely dilated, and insensible.	Recovery complete in a week, gastritis following.	
18	Lond. Lancet, vol. ii., p. 7,	George Harley, M.D. 1863.	Female, 12 yrs.	ʒ vj.	About 20 minutes.	Became imperceptible at wrists.	Stertorous, reduced to six in a minute.	Contracted.	Recovery complete in 10 days.	Chloroformic anodyne.
19	Med. Times and Gazette, Lond., vol. ii., p. 378, 1863.	W. B. Woodman, M.D.	Male, 72 yrs.	Nearly ʒ j.	1 hour.	Impercep- tible.	Slow, imperceptible.	Contracted.	Recovery in 2 days.	Liniment of chloroform and olive oil.
20	Australian M. J., Melbourne, vol. ix., p. 108, 1864.	F. Dowling.	Male, 28 yrs.	ʒ jss.	.....	Small, fast, and failing.	Slow and stertorous.	Dilated.	Death in 27 hours.	Autopsy.
21	L'Union Medicale, Paris, vol. xxiii., p. 155, 1864.	Dr. Martinenq.	Male, 40 yrs.	10 gms.	.....	.....	.....	.....	Recovery.	
22	Gaz. Med. de Strasbourg, p. 168, 1864.	Dr. Macker.	Male, 27 yrs.	50 gms.	½ to ¾ hours.	100, very feeble and small.	Stertorous, stopped at times.	Enormously dilated.	Recovery.	
23	Med. Times and Gazette, Lond., vol. i., p. 34, 1866.	Edward Bradford.	Male, 25 yrs.	ʒ j.	2½ hours.	At wrist scarcely to be felt; heart, pulsations about 120.	Stertorous, short and jerky, 20 in a minute. at times they almost ceased.	Contracted.	Death in 12 hours.	Autopsy.
24	Med. Record, N. Y., vol. ii., p. 54, 1867.	O. D. Pomeroy, M.D.	Female, 45 yrs.	ʒ v. to ʒ ix.	3 hours.	About 70, and feeble.	.....	.....	Death on eighth day of acute gastritis.	Autopsy.
25	Leavenworth Med. Herald, vol. i., p. 49, 1867.	D. W. Stormont, M.D.	Male, 26 yrs.	ʒ ij.	About 1 hour.	.....	Stertorous.	.....	Died in 1 hour.	Autopsy.
26	West. J. M., Indianapolis, vol. ii., p. 720, 1867.	J. E. Tefft, M.D.	Male. 28 yrs.	ʒ ij.	2 hours.	80, strong and full, became more frequent and feeble, and finally absent.	Stertorous and labored.	Natural, became dilated.	Recovery complete in a week.	
27	Pacific M. and S. J., San Fran., vol. ii., p. 499, 1868.	I. R. Prevost, M.D.	Female, adult.	ʒ ij.	2 hours.	Rather full and accelerated, soon became pulseless.	Stertorous.	Dilated.	Died in 19 hours.	

Table of Cases of Poisoning by the Internal Administration of Chloroform (Continued).

No.	Reference.	Reporter.	Sex.	Quantity taken.	Time elapsed before seen.	Pulse.	Respiration.	Pupils.	Result.	Remarks.
28	Deutsche klin. Biol., Bd. xxi., p. 196, 1869.	E. Fitzau.	Male, 57 yrs.	90 gms.	3 hours.	Small and intermittent, became regular.	Impeded.	Widely dilated, insensible to light.	Death in 29½ hours.	
29	Australian M. J., Melbourne, vol. xvi., p. 108, 1871.	J. F. Neild, M.D.	Male, 28 yrs.	℥j.	½ hour.	Too small to count.	Labored and interrupted.	Widely dilated.	Death in 60 hours.	Antopsy.
30	Australian M. J., Melbourne, vol. xvi., p. 108, 1871.	— Blair, M.D.	Female, adult.	℥ij.	.....	.....	.....	.....	Recovery.	Related in discussion of No. 29, Med. Soc. Vict'a. (case of 1865)
31	Australian M. J., Melbourne, vol. xvi., p. 210, 1871.	W. C. Rees, M.B., M.R.C.S.E.	Male, 13 yrs.	℥ss.	4½ hours.	100, feeble and irregular.	Sighing and laborious.	Dilated ⅗	Recovery complete next day.	
32	Phila. Med. Times, vol. i., p. 277, 1871.	A. Fricke, M.D.	Female, 45 yrs.	Tablespoonful.	Immediately.	.....	.....	.....	Recovery.	
33	Med. and Surg. Rep., Phila., vol. xxiv., p. 495, 1871.	S. M. Snyder, M.D.	Male, adult.	About ℥xij.	¾ hour.	80 to 88, feeble.	40, quick and somewhat difficult.	Dilated, then varied.	Recovery, with gastro-enteric symptoms following.	
34	Deutsche klin. Biol., xxiii., p. 415, 1871.	Bd. H. Böttger.	Female, 58 yrs.	30 gms.	Immediately.	Pulseless.	Intermittent.	.....	Recovery.	Ether and chloroform, each 30 gms.
35	Indian Med. Gazette, Calcutta, vol. viii., p. 182, 1872.	Banergie, Sub. Asst. Surg.	Male, 40 yrs.	About ℥j.	4 hours.	Exceedingly feeble, and almost imperceptible.	Heavy and stertorous.	Contracted.	Recovery in 8 hours.	
36	Am. Jour. Med. Sc., Phila., vol. lxiv., p. 430, 1872.	S. C. Busey, M.D.	Female, 4 yrs.	Teaspoonful.	½ hour.	Almost imperceptible.	Short, quick, irregular, and superficial.	Contracted.	Recovery complete in 4 hours.	
37	Am. Jour. Med. Sc., Phila., vol. lxiv., p. 431, 1872.	S. C. Busey, M.D.	Female, 30 yrs.	℥iij.	1½ hour.	78, small and very weak.	16, very superficial, every fifth long drawn and full.	Contracted to a point, and insensible to touch. Nothing peculiar.	Recovery complete next day.	
38	Med. Arch., St. Louis, vol. viii., p. 79, 1872.	J. C. Whitehill, M.D.	Female, 50 yrs.	℥ss.	15 to 20 minutes.	Quick, feeble, and almost indistinct.	Labored.		Recovery.	
39	Atlanta M. and S. Jour., vol. x., p. 236, 1872.	J. T. Johnson, M.D.	Female, adult.	Nearly ℥vj.	½ hour.	80, full.	36, imperfect.	Dilated.	Recovery in 3 or 4 days with slight gastritis.	
40	Arch. f. klin. Med., Leipg., Bd. x., p. 309, 1872.	Dr. Degen.	Male, 48 yrs.	℥j.	3 hours.	Slow, full, regular.	Slow and regular.	.....	Recovery.

respiration stopped for thirty seconds. Treatment: Stomach-pump and sinapisms. Gastritis followed and she died on the eighth day after taking the poison. Post-mortem examination showed congestion and ulceration of the stomach.

Case 14.—Julia W——, aged eighteen, took one ounce. Seen in twenty minutes. Fell to the floor; burning pain in stomach; pulse feeble and quick; countenance pallid; extremities cold; became gradually comatose; breathing stertorous; pupils contracted and insensible to light. Refused to take medicine. Treatment: ℥j. powdered ipecac was forced down her throat, vomiting followed. Mustard to extremities, cold water dashed on face, and flagellations at short intervals. In three hours she was entirely recovered. Case of attempted suicide.

Case 15.—Adult male, aged twenty-eight, was found in a semi-comatose condition. Had attempted to disembowel himself; had shot himself in each side of the chest, and stated that he had taken one-fourth pound of chloroform. Taken to hospital. No smell of nor any symptoms of chloroform poisoning. Was seen in two hours. Death.

[This case is abstracted from a newspaper report, contains no physician's name, and is of very doubtful authenticity.—L. E.]

Case 16.—Mr. P. M——, aged thirty-five, between 12.15 P.M. and 7.15 A.M. (in seven hours) took about an ounce and a half. When seen pulse full, though slow; respiration hurried and audible; pupils highly dilated and gave no evidence of sensibility. Treatment: Fresh air, ice-bladders to head, cold effusions along the spine, and a common enema; electricity; warm jars to feet; lavement, with the addition of twelve to fifteen drops of caustic ammonia was given and retained. There was partial return of sensibility. Death occurred at a quarter to twelve, midnight, twenty-three and a half hours after taking the first dose. Post-mortem examination showed congestion of brain, lungs, and stomach.

Case 17.—Mr. ——, aged fifty, on April 6, 1862, took two ounces. Seen seven hours after. Condition: Deep coma; pupils widely dilated and insensible; pulse slow and feeble; body colder than natural; movements of thorax scarcely perceptible; sensation generally abolished. Treatment: Ammonia, sinapisms, bottles of hot water, and cold affusions, without apparent benefit; stomach-pump tube introduced, stomach evacuated of chloroform, mucus, and watery fluid. Patient soon showed signs of returning consciousness, and in two hours was able to give rational answers. In a week he had entirely recovered from the gastritis which followed.

Case 18.—M. A. McG——, aged twelve, on January 10, 1862, took six drachms of chloroformic anodyne. Seen in about twenty minutes (approximated time, E.). Felt sick and vomited; was in a deep stupor in ten minutes, perfectly insensible; pupils contracted; face livid; breathing stertorous, reduced to six a minute; pulse became imperceptible at wrists. Treatment: Stomach-pump, then, three hours after, an injection into the stomach of a pint of hot coffee with three drachms of spirit of nitric ether, and repeated; cold stream of water to the head. In fifty-four hours she was up and able to walk across the room. She suffered about ten days from bronchitis, the result of the cold water. The chief ingredients of chloroformic anodyne are: strong solution of opium, some chloroform, and a few drops of hydrocyanic acid (prussic acid odor was perceptible in the vomited liquid).

Case 19.—An Irishman, aged seventy-two, took, on February 20, 1863, nearly an ounce (wineglassful of a liniment composed of chloroform and sweet oil). Seen in one hour. Insensible; cold; slow, imperceptible respiration; pallid face; imperceptible pulse; pupils contracted. Treatment: Emetics; stomach-pump; internal stimulants, coffee and brandy; hot bottles to feet. Recovered on second day.

Case 20.—R. K——, male, aged twenty-eight, on February 16, 1864, at 2 P.M., took an ounce and a half. Body cold; breathing slow and stertorous; pulse small and fast failing; pupils dilated. Treatment: Stomach-pump. Death at nine o'clock on the 17th (in twenty-seven hours). Post-mortem examination showed: Brain and membranes much congested; lungs congested; heart natural; mu-cous membrane of stomach and duodenum much congested.

Case 21.—Male, aged forty, took ten grammes. "I felt at first an acrid taste with a constriction of the windpipe, then quite a painful heat in the epigastric region; then followed a grinding pain in the intestines, finally a desire to have a passage, which was accompanied by a smarting and strong intestinal pains at the anus." He had taken some Seidlitz water in the morning. Treatment: Emollient and albuminous drinks, oil injections, and fresh air. Recovered.

Case 22.—Male, adult, aged twenty-seven, on October 29, 1863, took fifty grammes. Seen in half an hour. Had vomited. Dorsal decubitus, completely immobile; skin discolored and cool; extremities cold; eyes convulsed and turned up; pupils enormously dilated; respiration stertorous; pulse, 100, very feeble and small; heart-beat short and clear, at times tumultuous. Unconscious. Respiration ceased from time to time. Treatment: Heated iron to chest, frictions to all parts of the body; titillated pharynx with feather; artificial respiration; injections of strong infusion of coffee; internally strong coffee and aqua ammonia. Some gastritis and icterus followed. Recovered.

Case 23.—Male, aged twenty-five, took, on November 25, 1865, one ounce. Seen in two and a half hours. Complete insensibility; countenance pale; lips livid; pupils contracted; breathing stertorous; body warm; pulse at wrist scarcely to be felt; pulsations at heart heard and felt, about 120; respirations short and jerky, 20 in a minute, at times they almost ceased; unable to swallow. Treatment: Attempted to excite vomiting by feather; strong ammonia to nostrils; cold water dashed on face with no effect; stomach-pump tube introduced induced suspension of respiration and pulse, and was abandoned; ammonia to region of heart, legs, thighs, nape of neck, and spine without good effect; injections of hot water and turpentine thrown into the rectum. There was slight improvement, but death took place twelve hours after taking. Autopsy showed congestion of lungs and cardiac vessels. (This was a case of supposed chloroform-poisoning; the amount taken was approximated. "The coroner's jury were unable to come to a decision as to the immediate cause of death."—L. E.)

Case 24.—Mrs. D——, aged forty-five, recovering from a drunken debauch, took, with suicidal intent, from five to nine drachms. Seen in three hours. Profound coma; extremities cold; pulse about 70, and feeble. Death seemed so imminent that no efforts were made to counteract the drug. The chloroform produced sleep in a few minutes after taking it. In three hours more (six all told) she had somewhat reacted. In seven hours she had recovered consciousness. Acute gastritis set in and she died on the eighth day. Was jaundiced on the fourth day. Autopsy: Left lung collapsed and slightly adherent to pleura, right in state of gray hepatization; liver normal in size, fatty, presenting signs of commencing cirrhosis; kidneys normal in size and a little granular; œsophagus, nothing worthy of notice; stomach, fulness of blood-vessels, spot of extravasation on inner wall, nearly an inch in diameter; its mucous membrane at this point seems to be destroyed. Gastritis was the cause of death.

Case 25.—Mr. G. H——, aged twenty-six, took two ounces. Seen in one hour, a few minutes before his death. In three minutes (estimated time) he could with difficulty be aroused from the stupor into which he was sinking; could not speak, but indicated that he had severe pain in the stomach. In five minutes he was entirely unconscious, lying still, breathing stertorously

Medical assistance arrived too late to be of service. Post-mortem examination showed congestion of lungs, œsophagus, and stomach. Mucous membrane could be pulled off with the finger-nail.

Case 26.—Male, aged twenty-eight, took two ounces undiluted. Seen in two hours. Profound coma; pupils natural but insensible to light; pulse about 80, strong and full; breathing slightly stertorous. In two hours the pulse became frequent and feeble; respiration gasping and stertorous; pupils dilated; pulse became entirely absent at wrist; breathing very labored. Treatment: Sinapisms; dry heat; friction to extremities; administration per rectum of brandy and carbonate of ammonia; hot brandy and hot turpentine to the spine. Gastritis followed, but was recovered from in a week.

Case 27.—Female, adult, with suicidal intent, took two ounces (approximated, L. E.). Seen in two hours. Most profound insensibility; lips and face cool and bluish; extremities still warm; breathing stertorous; pupils dilated; pulse rather full and somewhat accelerated. A physician had been called, but pronounced the case hopeless and had abandoned it. Deglutition was impossible. Drew forward the tongue, ventilated the room, dashed cold water in the face, and had the extremities rubbed with hot mustard-water, ammonia occasionally applied to the nostrils; galvanic battery; injections of warm infusion of coffee, and hot bottles to the feet. She grew worse, becoming soon entirely pulseless, extremities icy cold, conjunctiva injected, and pupils still more enlarged. Application of galvanism continued; in an hour the breathing had lost its stertor, and she opened her eyes at intervals. Injection of coffee and brandy, and external stimuli. She regained sensibility slowly; the stomach rejected brandy and coffee. Pulse could not be detected at the wrist. Hemorrhage from the bowels. Given aromatic spirits of ammonia and tincture of larch. Her bowels had moved three or four times. Death in nineteen hours. Autopsy not permitted.

Case 28.—Physician, aged fifty-seven, took ninety grammes. Vomited; deep sopor came on. Was bled and cold applied to head. Dr. Fitzau arrived in three hours. The extremities were warm; there was complete anæsthesia; total paralysis; heart weak, every third beat intermittent; respiration impeded; bowels distended with gas; pupils insensible to light and widely dilated. Stomach-pump. Pulse became regular. Owing to the paralysis, when the tongue, which had been held out, was let go, the respiration ceased. Sensibility was completely restored. Severe gastritis followed. Death in twenty-nine and a half hours. Post-mortem examination not permitted.

Case 29.—Adult, male, aged twenty-eight, on March 27, 1871, took one ounce. Seen in half an hour. Insensibility; breathing labored and interrupted; pulse too small to count; pupils widely dilated; extremities cold; anæsthesia complete. Salt-and-water emetic, followed by vomiting. Stomach-pump, hot bottles to feet and sides, and covered with blankets; injections of ammonia into median-cephalic vein, repeated. Improved, but died in sixty hours. Autopsy: Brain congested; right lung and pleura congested; lower part of trachea congested; œsophagus congested; mucous membrane of stomach congested.

Case 30.—Female, adult, took two ounces. Given sulphate of zinc, then aromatic spirits of ammonia. Recovery. This was related in the discussion upon the preceding case.

Case 31.—Boy, aged thirteen, on May 25, 1871, took half an ounce. Seen in four and a half hours. Comatose; respiration sighing and laborious; pupils dilated two-thirds; pulse feeble and irregular, 100 to the minute; extremities cold; no convulsions; vomited. With stomach-pump threw in one drachm of sulphate of zinc, and repeated; given coffee and carbonate of ammonia. Recovered, and returned home next day.

Case 32.—Mrs. H——, aged forty-five, took a tablespoonful in water for liq. ammon. acetat. Was instantly given a pint and a half of lukewarm water; vomiting followed. Complained at once of burning sensation; in eight minutes she was unconscious. Bowels and bladder evacuated involuntarily. Brandy freely given, also salad oil and yolk of egg. In the afternoon much improved, but very feeble.

Case 33.—Male, adult, took about twelve drachms. Seen in three-quarters of an hour. Insensible; pulse 80 to 88 and feeble; pupils widely dilated; breath highly charged with chloroform, and respiration 40, quick and somewhat difficult. During the first four hours the pupils remained dilated, then dilated and contracted every few minutes and not affected by strong light. Pulse remained about the same throughout. The respiration was affected singularly. When the body rested on the right side with the head drooping forward and downward it would be about 40 and regular. If the body were placed on the back it would be entirely suspended. The face was livid, the lips red and dry. Cutaneous surface during first six hours was natural, during the last two covered with free perspiration. Comatose condition lasted eight hours. Treatment consisted in free ventilation, cold applications to the head, and whenever the respiration was arrested forcing the finger up under the diaphragm. After consciousness had returned symptoms of gastro-enteric inflammation were present. He recovered completely.

Case 34.—Frau N. N——, aged fifty-eight, took thirty grammes each of sulphuric ether and chloroform. Seen immediately. Præcordial anxiety; pulseless, senseless, and with intermittent respiration; skin was bleached, cyanotic; paralysis general. Had vomited. Artificial respiration; faradization to nervous phrenicus for two hours, when this was stopped the respiration stopped; it was continued for six hours. Sensibility returned. Was given a subcutaneous injection of strychnine. Recovery was complete.

Case 35.—A jemidar, aged forty, on March 26, 1872, took about one ounce at 4 A.M. to poison himself. Seen at 8 A.M, four hours later. Condition: Perfectly insensible, with half-shut eyes and contracted pupils; countenance pale; breathing heavy and stertorous; pulse exceedingly feeble, almost imperceptible; all the muscles relaxed and there was no sensation. Stomach-tube introduced and about two pints of water containing twenty grains of sulphate of zinc injected. Stomach washed out several times. Brandy and ice given. In eight hours he walked away unassisted.

Case 36.—Female, aged four, on May 28, 1872, took a teaspoonful. Seen in half an hour. Appeared as one partially intoxicated. Had been given teaspoonful of olive oil, this was followed by draught of warm water. Vomiting soon followed; sank quickly into profound coma; pallor of features; sunken eyes, contracted pupils, insensibility of cornea; unusual muscular relaxation; complete anæsthesia; coldness of extremities; almost imperceptible pulse; short, quick, irregular, and superficial breathing. Treatment: Elevated chest, lowered head; artificial heat; small quantities of brandy. Deglutition interrupted, slow, and difficult. Artificial respiration. Consciousness returned in one hour, and in four hours she was entirely recovered

Case 37.—Female, aged thirty, took three drachms. Seen in about an hour and a half. Convulsions; intense pain in the abdomen; perfectly insensible; pupils contracted to a point, corneæ insensible to the touch; universal anæsthesia; extreme pallor of face; cold hands and feet, general surface cool; pulse 78, small, very weak; respiration 16, very superficial, every fifth respiration long-drawn and full. Treatment: Emetic of warm water and salt and mustard; ice to spine; brandy internally. Recovery complete in one day. In this case the patient had taken chloroform, ʒ iij.; tinct. camphor, ʒ iij.; and tinct. opii, ʒ jiss., in addition to ʒ ij. of tinct. of opium.

Case 38.—Tillie ——, aged fifty, took half an ounce for lime-water. Seen in from fifteen to twenty minutes.

Breathing labored; pulse quick and feeble, almost to indistinctness; impossible to arouse her; surface covered with cool perspiration; nothing peculiar about eyes. Treatment: Fresh air, frictions to extremities, warm milk and lime-water freely, with whiskey or brandy and ammoniated tincture of valerian. Gastritis for several days following.

Case 39.—Woman, took nearly six drachms. Seen in half an hour. Pulse 80 and full; respiration 36 and imperfect; pupils dilated. Treatment: Enema of one ounce spirit vini gallici; three-fourths grain morphia subcutaneously. The effect was immediate and marked; patient rallied, but depressive sinking again threatened in an hour or two, to be as promptly relieved by a repetition of the treatment. Six hours after swallowing the chloroform she gave the first sign of consciousness. Gastritis followed for three or four days.

In the discussion which followed Dr. Wilson stated that he had seen a man supposed to have taken four ounces; he appeared wild and excited, as if he had been on a spree (Report Atlanta Academy of Medicine).

Case 40.—Adult male, aged forty-eight, took one ounce. Seen in three hours. Respiration slow and regular; pulse slow, full, and regular; stomach emptied at time of taking by vomiting. After twelve hours sensibility returned. Complete recovery. No bad effects followed.

Case 41.—Adult female, took one ounce. Seen in a few minutes. Pulse almost gone, face livid; deglutition impossible. Treatment: Lowering the head of the bed and the use of ammonia externally with friction. Recovery with slight gastritis.

Case 42.—T. D——, male, aged sixty, took ℥ ss. Seen in ten minutes. In five or six minutes became insensible; respiration shallow and prolonged; pulse at wrist so feeble as to be almost imperceptible. Mustard to pit of stomach, nape of neck, and calves. Paralysis of sphincter ani, ammonia and brandy not retained. Respiration became feeble and expirations cold; artificial respiration. In about two hours after taking the chloroform he was able to sit up and take some weak brandy-and-water. No bad effects followed.

Case 43.—C. McK——, admitted to Royal Free Hospital, October 20, 1877. Had taken one ounce and a half from 6.30 to 7.15 P.M. Seen in forty-five minutes. Unconscious; breathing irregular and occasionally stopped; pulse very intermittent; pupils dilated and fixed. Teatment: Stomach-pump, artificial respiration, and galvanism; nitrite of amyl on lint without effect; enema of three drachms aromatic spirits of ammonia; brandy and milk. Died about 8.45 P.M., October 21st. Autopsy showed lungs intensely congested; stomach congested; intestines, first five feet congested, vessels of intestines generally congested; peritoneum and omentum congested; other organs normal.

Case 44.—German woman, aged twenty, took one ounce. Seen in five hours. Deep stupor; pulseless and fast sinking. Treatment: Electricity of no use. Nitrite of amyl inhalations same. Hypodermic of digitalin, one-tenth grain, over scorbiculis cordis, repeated in an hour, then one-tenth grain of atropia an hour later. Recovery without gastric or œsophageal trouble.

Case 45.—Young lady, took six drachms. Seen half an hour after. Thoroughly anæsthetized; respiration nearly normal; pulse 80. Had vomited, and vomited again on arrival of Dr. Ingals. Respiration became inefficient and pulse failing. Inhalations of ammonia and one-twentieth grain of strychnia sulphate given hypodermically, a second one of one-fortieth grain in about three-quarters of an hour. Respiration ceased so that life was only sustained by artificial respiration. Electricity to nape of neck, the other pole to the pit of the stomach and various parts of the chest. Recovered consciousness in five hours after taking the drug. Nausea and vomiting were the only bad effects.

Case 46.—Male, aged twenty-three, from 9 to 11 P.M. took two and a half ounces. Seen in eight to ten hours. Pale; pupils dilated and fixed; breathing slow, shallow, and at long intervals; pulse not to be felt anywhere; heart-sounds could not be heard by stethoscope; trunk warm, extremities cold. Warm brandy-and-milk injected into bowels; sinapisms, frictions, artificial respiration. Recovery from chloroform, but died on third day by hanging, from depression of spirits. Autopsy showed lungs congested.

Case 47.—R. S——, male, aged twenty-seven, on August 16, 1879, took three grammes. Seen in two hours. Pulse 72, full, soft, normal probably; respiration full, deep, quiet; pupils dilated; no danger apprehended. Recovery next day. August 19th, 7 A.M., jaundiced; respiration labored; pupils widely dilated; no pulse at wrists; temperature 36.70° C. in axilla. Death at 4 P.M. There is much doubt about this case. Autopsy afforded no evidence. Dr. O'Connell does not think it was chloroform, but phosphorus.

Case 48.—Adult female, on January 17, 1879, took fifty to sixty grammes. Seen in about four hours. Deep intoxication; artificial respiration. Respiration returned, but difficult and stertorous; pulse at radials imperceptible, at temporals and carotids thready; extremities cold and rigid; strong contraction of jaws. Titillation of pharynx, cold affusions and flagellations. Pulse became stronger. Given strong coffee and acetate of ammonia. Gastritis followed. Died (9 A.M. on 18th) in thirty-one hours. Autopsy showed ulcerations in pharynx, œsophagus, stomach, and intestines; mucous membrane of œsophagus corroded in its whole length; ulcerations of stomach small, of intestines enormous; lungs intensely congested.

Case 49.—Female, adult, took about one ounce. Not seen for several hours. Profound narcosis; stertorous breathing; cheeks and face pallid and cold; the eyes remained open or shut as they were left; pulse 80, weak; respiration 45 per minute, and difficult. Thermometer in axilla registered 94.70° F., taken three times; in the vagina it registered 95.2° F. Treatment: Caffeine hypodermically and per orem, then hypodermics of strychnia, and whiskey with carbonate of ammonia (ammonia carbonate one gramme dissolved in one drachm of whiskey), followed quickly by strychnia sulphate, gr. $\frac{1}{15}$. Recovered.

Case 50.—Laborer, aged sixty, took liniment of chloroform and oil, each twenty grammes, at 3 P.M. At 3.30 P.M. unconscious; stertorous respiration; cheeks, lips, and tongue highly cyanosed; whole body in viscid perspiration; pulse 72, moderately full and rhythmic; pupils highly contracted; cervical veins distended. No reflex excitability; vomited once. Stomach-pump brought away chloroform-smelling yellow fluid; stomach washed out. Pulse dicrotic; respiration labored; conjunctivæ insensible. Tongue drawn out, respiration became easier; ammonia to nostrils; cold frictions; black coffee introduced into stomach by pump; involuntary evacuation of the bowels; vinegar enema. 5 P.M.: Spontaneous cough. In removing mucus from mouth, brought out tobacco-quid not observed before. 5.15 P.M.: Semi-conscious. Twenty-four hours afterward chloroform-smell from contents of stomach drawn through pump.

Case 51.—Frenchman, took three ounces. Seen in an hour and a half. Respiration had ceased; pulse twenty per minute and hardly felt at wrist; surface cold and of dusky pallor; lips livid; pupils widely dilated. Treatment: Artificial respiration; magneto-electric machine; enemata of beef-tea and brandy; subcutaneous injections of ether over heart. Inhalations and subcutaneous injections of nitrite of amyl gave but temporary relief. Recovered.

Case 52.—Adult female (about a tablespoonful) half ounce. Severe convulsions; burning pain in stomach. Morphia sulphate, gr. $\frac{1}{4}$ hypodermically. Only sequelæ were burning of mouth and throat.

Case 53.—Adult female, took half ounce of toothache-

drops composed of equal parts of chloroform and laudanum. Only bad result burning of throat and mouth.

Case 54.—Adult female (old) took one drachm. In five minutes had convulsions. Hypodermic of morphia sulphate.

Case 55.—Louise R——, aged six, in December, 1883, took two drachms Squibb's chloroform undiluted. Seen soon after. Respiratory efforts very feeble; heart-beats scarcely perceptible; conjunctivæ not responsive; teeth clenched; limbs fell listlessly where placed; cold and nearly pulseless. Had been given emetic of sulphate of zinc; vomited. Artificial respiration and electricity over phrenic nerve; after improvement, cracked ice, stimulants and keeping patient awake were the measures employed. Recovery complete in a few hours. [In a communication from Dr. McArdle, he states he saw this patient in about half an hour.—L. E.]

Case 56.—"The patient was a female, twenty-one years of age, who had swallowed two ounces of pure chloroform. She was found within twenty minutes afterward in a deep stupor; the pupils contracted; respiration regular; pulse 70, soft and full; the face not congested. External irritants were applied; the stomach-pump used, and brandy and ammonia given. The respiration then became slow and stertorous, the pulse fell, and the face became livid. Galvanic shocks were employed and continued for two hours, with stimulating enemata, and heat to the limbs. The respiration fell to two in a minute; the pulse at the wrist was almost imperceptible. The remedies were persevered in, and reaction gradually took place. In five or six hours . . . consciousness returned. On the following day there was thirst, nausea, pain in the abdomen and lumbar region, and frequent and bloody stools. In about a week recovery was complete."

[Note: This case is extracted from Stillé's "Therapeutics and Materia Medica," vol. i., p. 194, ed. 1860, as the volume of the "Annuaire de Thérap." is not on file at the Library of the Surgeon-General's office. I think it corresponds to Case No. 6 by Spence.

June 7, 1885.

TREATMENT OF LOOSE CARTILAGE OF THE KNEE-JOINT.

By ALEXANDER HADDEN, M.D.,

NEW YORK.

For the treatment of loose cartilage in the knee-joint there have been devised, baring the radical cure by direct or indirect incision, several means, none of which have proven as efficacious as the method which I have adopted in the following case.

About a year ago Mr. G——, aged fifty-five, consulted me concerning a loose cartilage in his knee-joint, for which he had sought advice from many of our prominent surgeons in this city, none of whom, except by operation, could offer him any positive alleviation from this troublesome affection.

Often, he stated, while walking through the streets, he would be suddenly seized with a pain in the joint so severe that he would fall to the ground entirely helpless. He had tried all the palliative methods recommended by the surgeons whom he had consulted—such as posterior splints, plaster-of-Paris bandages, elastic knee-caps, and even absolute rest for some months at a time—none of which remedies prevented the cartilage from slipping down and being caught between the articular surfaces of the bones of the joint and causing him this excruciating pain. Upon physical examination I found the joint swollen and very tender, and by a little manipulation could detect a small cartilaginous ovoid body (about half an inch by three-fourths inch) under my fingers, which could be pushed from one position to another without much difficulty when the leg was extended.

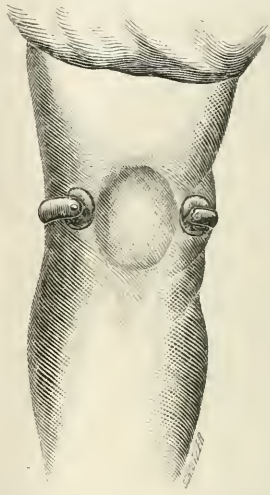
As long as the leg was flexed the cartilage could not be displaced, but was fixed in the position where it was, held by the surrounding structures then in a tense condition.

When the leg was extended I could push the cartilage up, by the side of the patella, around in the synovial sac, beneath the tendons of the quadriceps extensor muscles and accessory band of the vastus internus, down the other side of the patella and back again.

There seemed to be a canal through which this little body bobbed up and down and in and out of the joint-cavity. The bandages which had been applied relieved him as long as he did not walk about.

As his business required him to be up and about, and as he did not wish to run the risk of an operation, which the surgeons pronounced hazardous, he consulted me to find out if I could not do something for him.

By manipulating the cartilage I got it up beside the upper border of the patella, and thought if I could only keep this little body in that position, and retain it there by some appliance which would at the same time occlude the passage through which it got down into the joint, I would have accomplished the desideratum, which rest, splints, and bandages failed to do.



Accordingly, the most practical appliance I could obtain at the time for this purpose was an infant's double truss, placed so that the two pads pressed upon the lower end of the femur between the condyles and the patella, with the greatest pressure on the former bone. This fitted it quite well, and demonstrated the practicability of my idea.

I accordingly gave orders to have a single steel spring made with pads to press on each side of the patella, as shown in the above figure; the curvature of the spring being so formed as to clear the popliteal space behind and so as not to interfere with flexion of the leg, and of sufficient strength to close the canal while the limb was in a straight position.

A small strap may be fastened to the pads over the patella, and tightened to suit the convenience of the patient, and which may help to keep the spring in a more fixed position; this, though, is not entirely essential. This apparatus has so far succeeded that from the time of its application to the present day the cartilage has never slipped down to give him trouble, and the patient has been about pursuing his business without the least inconvenience from it.

Homœopathic Pies.—The Boston *Traveller* tells the following on the authority of a truth-telling auctioneer of that city: "A year or more ago, the auctioneer had for sale a lot of homœopathic medicines. All these medicines were dumped into one pile, and disposed of in one lot, there being various kinds of medicines in the mass. A boarding-house keeper bought the lot, and some days after the purchase, the auctioneer asked her, 'What did you do with that homœopathic medicine, Mrs. ——?' She replied, 'I thought I could use it, and it was cheap and so I crushed it under the roller and then filled my sugar-bowls with it. The boarders seemed to like it, and especially when powdered over pies.'"

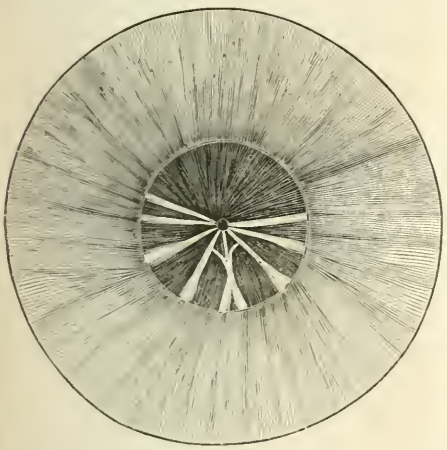
PERSISTENT PUPILLARY MEMBRANE.

By GEO. HOWE, M.D.,

COLUMBIA, S. C.

In your issue of April 4, 1885, Dr. F. C. Riley reports a case of persistent pupillary membrane which is very interesting, and which induces me to report a similar case which occurred in my practice in 1881.

F. T——, female, ten years old. O.D.V. $\frac{15}{40}$ by looking askance, O.S.V. perception of light, with questionable perception of form. By oblique illumination congenital cataract was discovered in the left eye. In the right eye there was a persistent pupillary membrane, which extended over the temporal half of the right pupil. It consisted of eight or ten bunches of fibres of a brown color, a shade lighter than the iris. These fibres united at the centre of the pupil. They were wider at the edge of the pupillary margin of the iris, and became more attenuated as they approached the centre of the pupil. Here they came together, forming a thickened point. Under the influence of atropia the fibres were lengthened, and became thinner.



The accompanying drawing was made from memory, and does not show the irregularities of the different masses of fibres.

Thinking that vision might be improved by breaking down the fibres, I introduced a stop-needle and tore them loose. They contracted promptly toward the iris. There remains, however, an opacity at the point of attachment to the lens capsule in the centre of the pupil.

Vision was improved sufficiently to enable her to read by holding her book so as to look through the clear portion of the pupil on either side of the central opacity.

The eyes do not seem over-sensitive, but tire somewhat after protracted use.

THE POWER OF DISINFECTANTS.—Volkmann says: "A surgeon who disinfects himself well, can immediately, after making a post-mortem examination, undertake any operation known to surgery. Every morning, from six to eight, during the summer I am obliged to give the students operations on the cadaver; and from ten to three I am busy in the hospital, operating and dressing wounds. I have never yet infected a patient. In the winter I have no operations on the cadaver. Comparing my results in the clinic, I can assure you that the mortality in summer is not greater than in winter." Says Esmarch: "If you have thoroughly disinfected yourself, you can immediatetely enter upon obstetric practice. Time does not destroy septic dirt."—*Medical News.*

HERPES OF THE THROAT.

By SOLOMON SOLIS-COHEN, A.M., M.D.,

SENIOR CLINICAL ASSISTANT AT THE THROAT DEPARTMENT OF THE PHILADELPHIA POLYCLINIC.

MR. W——, aged forty-five, presented himself at my class at the Philadelphia Polyclinic on May 29th. "He had been troubled," to use his own words, "for fifteen years with something that comes down in the throat and bursts. Sometimes it gets ulcered." It was a source of annoyance to him, causing unpleasant sensations of discomfort, heat, and dryness, and rendering speech and deglutition somewhat painful. This was his fourth or fifth visit to the clinic, but it was the first occasion upon which I had been able to see for myself the phenomena he so vaguely described. A somewhat close questioning of the patient had given me an inkling as to the true nature of the case; but as these instances are so infrequently met with, ocular demonstration is necessary to a positive diagnosis. Upon illumining the patient's mouth and throat by a strong light, a few scattered vesicles were noticed upon the soft palate, most of them of pin-head size, but one equal in size to three others. When the larger vesicle was punctured a drop or two of liquid escaped, and the walls of the vesicle collapsed. The case was, therefore, a genuine one of herpes of the palate, and was of extremely chronic nature. From the patient's manner and speech there could be no hesitation in classing him among those of decidedly neurotic temperament.

Chronic herpes of the throat occurs in this class of individuals, and is also occasionally found associated with a strumous or tuberculous diathesis, being then particularly obstinate. The initial manifestations of the disease are rarely seen. At first one or more minute papules are developed, isolated or in groups, upon the mucous membrane of the palate, of the tonsils, and exceptionally of the pharynx. Vacuolation of the superficial epithelium taking place, the papules are replaced by vesicles. These vesicles sometimes disappear by reabsorption of their contents. Usually, however, they soon rupture, leaving small superficial ulcers, which in some instances heal without a trace. As a rule, the ulcers become covered with fibrinous exudation, and, repair taking place beneath the exudation, it becomes disintegrated and detached, and no mark of the lesion is left. The patient remains free from annoyance for variable intervals—in this case a few days to three or four weeks—when the process is again repeated.

The acute form of the disease is not at all uncommon, but is often unrecognized. The vesicles are surrounded by an inflammatory areola. There is often decided pyrexia. Odynphagia is sometimes quite severe, the soreness of the throat and the local heat and dryness being more marked than in ordinary pharyngitis or tonsillitis. In some instances the attack is preceded by malaise and accompanied by depression.

I believe that many so-called mild cases of diphtheria are of this nature, and that the vaunting of indifferent remedies for diphtheria is not rarely due to the fact that during their exhibition cases of herpetic sore throat have recovered. The coalescence of several patches of exudation upon the surface of the vesicular ulcers gives rise to limited sheets of false membrane, apt to deceive the uninformed or careless observer.

Rarely, indeed, is a case of acute herpes of the throat seen in the papular or vesicular stage, and the diagnosis must be based upon the absence of the constitutional symptoms of diphtheria, the absence of glandular enlargement, the superficial character of the exudation, and its circumscribed location upon palate or tonsils. Some observers refer to the presence among the patches of exudation of small ulcers, such as ordinarily follow the rupture of the vesicles, or the appearance in isolated situations of small spots of false membrane, which indicate by their circular shape the previous existence of a vesicle, and by their transparency the recency of their formation.

In a case of acute herpetic tonsillitis which I had the opportunity of observing, the exudation presented, upon my first visit, as a number of scattered circular patches upon both tonsils. Upon the second visit, the tonsils appeared to be completely sheathed in a uniform false membrane. This is the only case I have seen at so early a stage. Sometimes herpes of the skin, of the lips, or of other mucous surfaces, co-exists with the throat affection. In some cases the differentiation from diphtheria is impossible even by the most experienced observer. Obviously the safest plan in such a case would be to treat as for the graver malady. The treatment of an undoubted case of herpetic sore throat is to be conducted on the principles applicable to inflammation of the mucous membranes of the throat in general. Rest, regulation of the diet, the administration of mild febrifuge and anodyne mixtures, with sedative inhalations when indicated by pain, may be supplemented during the detachment of the exudation by sprays of antiseptic and detergent solutions. Should a tendency toward phagedena become manifest, or genuine diphtheritic phenomena become superimposed, it will be necessary to employ more active measures appropriate to these conditions. The treatment of chronic cases consists in local applications, daily or every other day, of the dilute acids, and in the internal administration of such remedies as are indicated by the special diathesis of the patient; giving due attention to the regulation of his diet, the correction of any errors of habit, and the improvement of his general hygienic surroundings. Preparations of cinchona, of nux vomica, of arsenic, and of iron may be prescribed with advantage. In those of neurotic tendencies opium is said to have a specially beneficial action. As the stimulant rather than the sedative effects of the drugs are desired the doses must be small.

Clinical Department.

AN IMPROVED FRACTURE-BOX.

Dr. S. Bradbury, of Oldtown, Me., sends us a photograph representing the "box and railway" devised by himself for the treatment of compound fracture of the leg. The box is the ordinary fracture-box of every-day use, but the improvement consists in mounting it upon four grooved wheels riding upon two rails. He writes: "I have just removed the apparatus from a patient who had a compound comminuted fracture of the middle and lower third of the left leg, and I believe it the best apparatus for this kind of injury which we possess. The railway is screwed to the cross-bar at the foot of the bed, and rests upon a good hair-mattress. The leg is placed in the box, and imbedded in bran, which is retained in its place by a piece of sheeting laid in the box. The great advantage of the railway is that it prevents the ends of the upper and lower fragments from being crowded together by any movements of the patient during sleep. If the patient moves up or down, the box slides with the leg, and no harm is done. The attendants of the patient above referred to told me that this would often happen while he was asleep, the trucks riding to and fro over the rails without the least disturbance to the position of the leg in the fracture-box."

RHINOLITHS.

Dr. R. E. Beach, of Vandalia, Ill., writes that his attention was called recently to an article on this subject, by Dr. J. S. Bettman, in the *Journal of the American Medical Association*, and he was led thereby to send a report of two cases occurring in his own practice. Some twelve years ago a child was brought to him for advice concerning a catarrhal affection of the nose which had existed for eight months. The Doctor's suspicions having been aroused by the fact that the right side only was affected, he made a careful examination, and discovered a foreign body resting upon the middle turbinated bone. It was dislodged by slight traction with the forceps, and was found to be a rhinolith having a small seed for a nucleus. The second case was that of a little girl, four years of age, who had been suffering from a nasal catarrh for about eighteen months. The father asserted positively that the child had never introduced anything into the nose. Inspection showed an object lying on the floor of the right nasal fossa near the posterior termination of the inferior turbinated bone. The mucous membrane was much swollen, and covered completely the upper portion of the foreign body. The latter was slightly movable, and was supposed to be a detached sequestrum. Its removal being determined upon, the child was placed under chloroform, and the object was withdrawn by a hawk-bill forceps. It was found to be a calcareous body of oblong shape, three-fourths of an inch in its longest and one-half inch in its shortest diameter, and containing a cherry-pit as a nucleus. Dr. Beach says that he can recall numerous instances of the introduction of foreign bodies into the nostrils, and he insists upon the necessity of a careful and thorough examination of the nasal cavities in every case of catarrhal affection, especially when occurring in children.

ACUTE ALBUMINURIA OF POSSIBLY TRAUMATIC ORIGIN.

Dr. Walter F. Morgan writes that he was recently in attendance upon a boy, seven years of age, and had considerable difficulty in making a diagnosis until an analysis of the urine revealed the presence of fifty per cent. by volume of albumen. This condition had not been preceded by any of the specific fevers or other of the generally recognized causes of acute Bright's disease in children. "Possibly it may have been due to a fall upon the back, which the patient had had about a month before. The fall had been succeeded by a gradual deterioration in health, with great disturbance of the heart's action, convulsions, and cyanosis. During the convulsive attacks the heart-beats were irregular and about forty to the minute. An unfavorable prognosis had been given, but after a month of close attendance Dr. Phillips and myself had the pleasure of seeing convalescence begin. Diplopia and incoördination of the muscles of locomotion persisted for several weeks, but the patient is now in perfect health."

SALICYLATE OF IRON IN RHEUMATISM.

Dr. C. C. Duffy, of 263 West Fifty-fourth Street, writes to call attention to the value of salicylate of iron in the treatment of rheumatism, particularly when occurring in the subacute form. The impoverishment of the blood, so commonly occurring in the later stages of an attack of rheumatism, is to be attributed, he believes, not only to the disease itself, but also, when salicylic acid is exhibited, to the action of this substance upon the iron of the blood. He was in the habit, for a time, of prescribing some form of iron in alternation with salicylate of sodium, but met with no signal success. He then determined to exhibit the remedies in combination and has had most satisfactory results. He uses a mixture each dessertspoonful of which contains eight grains of salicylic acid, four grains of sodium salicylate, and one grain of ferrous malate. This is the usual dose, though sometimes even double the quantity is given. Dr. Duffy relates two cases of a number in which he has used salicylate of iron. The first case was that of an engineer, twenty-six years of age, suffering from an acute attack of rheumatism, involving both knees and ankles and the left elbow. The salicylate of iron mixture was given in dessertspoonful doses every four hours, and at the end of three days the patient was able to return to his busi-

ness and has remained well. The second case was one of an acute exacerbation of chronic rheumatism occurring in a domestic, twenty-two years of age. She had had her first attack some three years previously, and for the past six or eight months had never been free from pain, though able to perform her ordinary duties most of the time. The salicylate of iron mixture was given in the usual dose four times a day. At the expiration of about a month she was entirely relieved. In neither of these cases were any local applications made to the affected joints, nor were any other remedies employed. In a number of other cases a similar treatment was followed by equally good results, and in no instance was it necessary to resort to any other medication.

STRETCHING OF THE SCIATIC NERVE FOR SCIATICA.

Dr. Fraser C. Fuller, of this city, reports a successful case of sciatic-nerve stretching for sciatica. The disease was probably perineuritis, and for its relief the patient had been subjected to almost every known means of treatment. He was a man aged fifty, naturally strong and robust, but had become greatly reduced in strength and flesh. His sufferings were so intense that he was unable to sit at the table sufficiently long to take proper nourishment. The operation was performed November 16, 1884. The incision over the sciatic was made in the lower portion of the thigh, and the nerve readily found. Very slight tension, as compared with other cases, sufficed to give the sensation indicating that sufficient traction had been produced. The pain ceased immediately after the operation. Unfortunately, primary union was not obtained, and some suppuration ensued, perhaps explainable by the patient's low grade of vitality. A slight recurrence of the pain took place, but was cut short by the use of the Paquelin cautery. He has now been free from pain five months, and has increased over thirty pounds in weight. There appears to be a permanent condition of anæsthesia and numbness in the calf of the leg, probably due to rupture of the nerve-filaments, but it causes no inconvenience.

A NEW TREATMENT FOR VESICO-VAGINAL FISTULA.

Dr. B. Ruppe, of New York, recently read a paper before the Medico-Chirurgical Society of German Physicians, in which he described the circumstances which led him to the discovery of a novel method of treatment of this condition. He had been hastily summoned to attend a primipara, thirty-four years of age, who was in labor. She had had a severe chill and high fever the night before, and labor had commenced and the bag of waters had ruptured previous to his arrival. The pains were sluggish, and the presenting part could be felt only with the greatest difficulty. It was not until the following day that the pains returned with sufficient force to bring the head within reach, when the forceps were applied and the woman was delivered of a dead child. More notice was then taken of the other symptoms, and it was found that the woman was suffering from typhoid fever; and three days later it was discovered that she also had a vesico-vaginal fistula of sufficient size to permit of the introduction of the index-finger into the bladder. Dr. Loewe saw the case at this time, and it was determined to operate by Marion Sims' method after the patient had recovered from the typhoid fever. The patient being wretchedly poor and unable to provide the linen necessary for cleanliness, it became a problem how to obviate the irritation and other evil consequences following the constant dribbling of urine. Finally a large wash-tub was procured and provided with three pillows—one for the back, one for the knee-bend, and the third to sit upon.

The patient was placed in the tub, which was then filled with lukewarm water. The walls of the vagina were kept apart by means of a wire speculum. By means of this arrangement all the indications were fulfilled—the urine was prevented from irritating the parts, and the general temperature was brought under control by the bath. To the water, which was frequently renewed, was added at first an infusion of chamomile, but subsequently an oak-bark infusion was employed. The patient remained in the bath twenty-one days. During the third week, the patient frequently said that she had an inclination to urinate, and an examination the day after her removal from the tub revealed the fact that no fistula was present. Dr. Loewe appeared at the appointed time to assist at the operation, but was astonished to find nothing to operate upon.

"In the majority of cases," Dr. Ruppe says, "it would not be necessary to keep the patient in the bath longer than a week."

The method is especially applicable in cases in which an operation is contra-indicated, or in which it has been performed without success, or it might be employed in conjunction with the silver-suture method.

THE IMMEDIATE OPERATION FOR PARTIAL RUPTURE OF THE PERINEUM.

Dr. D. L. Gaillard, of Greenville, Tex., writes that, according to his experience, the chief cause of failure in the immediate operation for rupture of the perineum lies in the swollen condition of the parts immediately after parturition. The sutures are inserted and drawn as tight as the state of the tissues will permit, but in a short time they become loose, and apposition is not maintained. He relates a case in which this occurred, and in which he repaired the fault by a simple procedure. The patient was a primipara who had sustained an extensive lacerated rupture of the perineum. As soon as possible after delivery chloroform was given, and the edges of the wound were drawn into close apposition by quill sutures. The bladder was emptied by the catheter, and opium was given to prevent movement of the bowels. On the fourth day the swelling was so reduced that water, used in injection, together with the lochial discharge escaped between the lips of the laceration. Having prepared several little square pieces of lead, cut on one surface so as to form a clamp, Dr. Gaillard proceeded to tighten the sutures. Drawing the suture as tight as possible with one hand, the clamp, held in the teeth of a pair of pincers, was passed over the thread and held close to the quill. Then, when all the slack of the suture had been taken up, the lead was clamped. In this way the edges of the wound were again drawn into close apposition without disturbing the parts in any way. The parts had shrunken to such a degree that the sutures were shortened nearly an inch. The patient suffered subsequently from cystitis excited by the catheterization, but the wound healed readily without any further trouble. The writer does not favor silver sutures, but prefers the quill suture, as it is possible to draw it tight when required and thus keep the lips of the laceration together.

Fruit, Wine, and Tea.—In his recent Lettsomian lectures on Indigestion, Dr. Lauder Brunton declares acid fruit to be indigestible and apt to cause intestinal irritation. He believes sour wines to be peculiarly liable to cause indigestion, and, when taken regularly, to cause gastric catarrh. The tannin in tea interferes very considerably with the digestion of fresh meat, though such is not the case with dried meat, such as ham or tongue. Tea at breakfast is not apt to produce gastric disorders, but afternoon teas are pronounced bad. Infusions of tea should be "light drawn" and drained from the leaves before serving, as by this means only a small portion of the tannin becomes dissolved in it.—*British Medical and Surgical Journal.*

Progress of Medical Science.

The Treatment of Migraine.—Dr. Clifford Allbutt has found two drugs useful in the treatment of migraine. The first is guarana, given in two or three doses at short intervals. This is applicable to those cases which begin with some slight warning in the early day. Croton chloral is the other drug; this should be given in repeated doses until twenty grains in all have been taken. As migraine is a disorder that originates in childhood, the hope of a cure must be based upon a healthful life, a healthful growth, and a healthful education. With regard to tonics a combination of bromides with quinine has answered best; then come cannabis indica and ergot, and after these chloride of ammonium. The well-known fact that ocular anomalies may cause migraine is also duly emphasized by Allbutt.

Treatment of Acute Epididymitis with Fuller's-earth.—This substance was recommended some time ago by Professor Botkin, of St. Petersburg, in the treatment of aneurism, and of certain peripheral neuroses, and more recently Dr. Lukashevitch has employed it with success in the treatment of acute epididymitis. He makes the earth into a paste with water and applies it, spread upon cloth, to the inflamed testicle. It is necessary to renew the application two or three times in the twenty-four hours, and they are to be continued for from four to six days. Their almost constant effect was an alleviation of the pain within a few minutes, and at the end of two or three days the swelling began to diminish. The author attributes the good results obtained to the metallo-therapeutic properties of the clay, but it is not improbable that the cure was due to the constant moisture and pressure of the application rather than to any therapeutic properties residing in the substance itself.—*Gazzetta Medica di Roma*, April 1, 1885.

The Cumulative Action of Digitalis and Helleborе.—Dr. Van der Heide has recently undertaken a series of experimental investigations touching this much studied but yet imperfectly understood topic (*The Therapeutic Gazette*, May 15, 1885). In all cases in which digitaline and helleboreine were given in small or large doses, either subcutaneously or by the stomach, the following secondary appearances, lasting for as long as four weeks after the cessation of the administration of the drug, were observed: First, the pulse was in all cases slowed, only returning to normal after numerous fluctuations; second, irregularity of the pulse, which was more marked as an after-effect in those cases in which irregularity was a prominent symptom during the administration of the drug. When uniform doses were given for some time, in no case did the most powerful action on the heart occur after the first dose, and when the dose was gradually increased, the action on the heart became intensified, but without definite relationship to the increase of the dose; so that when the doses were rapidly increased, the effect is not as marked as would be expected from the size of the dose. From this it is clear that the action of digitaline and helleboreine on the heart is not a true cumulative one, but rather the heart becomes accustomed to the drug. The remarkable fact was further noticed by the author that when the administration of the drug is commenced with small doses, and these gradually increased, nervous disturbances are in nearly all cases observed, usually after the third or fourth dose has been administered. These symptoms last only one or two days, and then disappear, even if the drug is given continuously in the same doses, thus showing that the nervous system can also accommodate itself to the action of this drug. So, although this action is at first a true cumulative one, the nervous system rapidly becomes accustomed to the drug, even in a more marked degree than is the case with the circulation. We see, therefore, that while many facts determined by the author point to a cumulative action of these drugs, symptoms pointing to an accommodation of the organism are quite as marked. The following applications of these and other facts detailed by the author may be made as regards the employment of the drugs under consideration. It is better to give digitalis at intervals of twenty-four hours, and in small doses, rather than with smaller intervals and larger doses. Even when symptoms of cumulative action appear after prolonged use of digitaline or helleboreine, there is no great danger of a fatal or even serious result; for in all the author's experiments the toxic phenomena disappeared even during the continuation of the use of the drug. When, however, after the first day of the use of these drugs, no action appears on the heart, great care must be observed in the continuance of their use, since a further administration of the drug can produce the most dangerous symptoms or even death; thus in the author's experiments, in which death followed a small dose, no action appeared on the heart until the very time and occurrence of death. As regards the therapeutical value of helleboreine little is known, though that little seems to prove an absence of all useful properties in the treatment of heart diseases.

The Clinical Pathology of Chorea.—Dr. H. C. Wood, in the *Therapeutic Gazette*, May 15, 1885, publishes a clinical study of chorea, from which we extract the following points: "Precisely as at one time paralysis was supposed to be a disease, so at a later period was chorea believed to be a distinct affection. Indeed, many of the profession still use the term as though it were the name of a distinct ailment, and most of the treatises upon nervous diseases have a chapter upon chorea as a separate affection. It is, however, perfectly clear that the word should be employed as analogous to, or having equal rank with, paralysis or tremor. The term choreic movements is unnecessary; or, if it still be used, the term chorea should be considered to represent that condition in which choreic movements occur." There can no longer be any doubt that in acute human chorea alterations of the spinal ganglionic cells frequently exist. Dr. Wood says: "I do not mean to assert that an appreciable lesion of the spinal cells is always to be found in St. Vitus' dance; indeed, I am quite confident that the disease may prove fatal without such lesion. Nevertheless, I am well assured that such alterations are very frequent in fatal cases, and have in not a few instances been overlooked, because not appreciated and sought for. The marked tendency of the choreic movements to affect one side of the body, or one limb, has led many observers to confine their careful examinations to the brain, this hemi- or monoplegic tendency being believed to show that the movements originate in the brain and not in the spinal cord. A clinical study of the various human affections of the motor ganglia of the cord shows, however, that in such disorders spinal monoplegias are not at all uncommon, and that in some cases hemiplegias may be seen. In many cases of chorea of the dog this localization of the movements in one limb or in one side of the body is quite pronounced; indeed, this was the case in dogs in which I positively determined the spinal cord to be the seat of the lesion: it cannot, therefore, be considered that a hemiplegic, much less that a monoplegic, chorea is necessarily of brain origin." According to the evidence adduced by the author, "choreic movements in the child, as in the dog, may originate from a diseased condition of the ganglionic spinal cell. Further, as a diseased condition of the spinal ganglionic cells has been found in several cases of human chorea, it must be allowed that such diseased state is at least one of the fundamental pathological alterations of human chorea. It is perfectly clear, on the other hand, that the disorder is not confined to these multipolar cells. The researches of Dr. Putnam, already quoted, show that in the cat alterations may be found, at least in some cases, in the brain ganglionic cells, and every clinician knows that the cerebral functions are often profoundly affected in the

choreic child. The will, the intellectual and the emotional faculties are all prone to show the presence of an abnormal influence in chorea, and it seems, therefore, that we must consider that in the choreic child the ganglionic cells in the whole cerebro-spinal system suffer, and that this alteration is the base of the disease; or, in other words, the morbid pathology of chorea, or St. Vitus' dance of childhood, may be said to be a diseased condition of the ganglionic structures of the cerebro-spinal axis, which abnormal state may exist without alterations of structure sufficient to be determined by the microscope, or may go on until it is accompanied with marked structural lesions. Further, this condition must be looked upon as one of lowered tone, and it must be allowed that it may be produced by various causes, but is little prone to occur in persons of robust nervous system. The vital choreic depression of the nerve-cells may be the result of emotional disturbance, as in the chorea produced by fright. It may be the result of the influence of the rheumatic diathesis or poison upon the affected tissues. It may be the result of the partial occlusion of the circulation by cerebral capillary thrombosis or embolism, and there are probably other efficient causes in its production. The course of a chorea, as well as the severity of the symptoms, very naturally depends upon the cause of the abnormal condition, and hence we have the varieties so plainly marked in this so-called disease."

Multiple Myoclonus.—By this term Friedreich designates an affection which he observed in a lady fifty years of age. It consisted in clonic convulsive attacks occurring at irregular intervals in certain symmetrical muscular groups. The flexors and extensors of the forearms and legs were chiefly affected. The convulsions persisted during sleep, and were exaggerated by irritation of the skin. They were absent during voluntary movements. After existing for five years the affection disappeared spontaneously in the space of ten days. Friedreich believed that it was to be referred to a functional disturbance of the anterior ganglion cells of the cord.—*Rivista Clinica e Terapeutica*, May, 1885.

The Action of the Alkaloids of Quebracho Bark.—According to Harnack and Hoffmann (*The London Medical Record*, May 15, 1885), six alkaloids have been obtained from the bark of the aspidosperma quebracho. Four of these are crystalline—viz., aspidospermine, quebrachine, which presents the most beautiful crystals, quebrachamine, and aspidospermatine; and two amorphous—aspidosamine and hypoquebrachine. All these alkaloids produce in frogs respiratory paralysis, probably in consequence of annihilating the excitability of the respiratory innervation. Quebrachine acts in like manner most intensely on the respiratory centres of the mammalia; aspidospermine, however, in a less degree. They paralyze the central nervous system in frogs, gradually arresting the voluntary, and later, also, the reflex motion. Aspidosamine, when given subcutaneously in not too minute doses, brings on vomiting in mammalia, probably by its action on the corresponding nervous centres. The other preparations merely produce violent nausea. All these alkaloids also call forth symptoms of central irritation of the medulla oblongata. Paralysis of the peripheral terminations of the motor nerves has only been exclusively observed as the effect of aspidosamine and hypoquebrachine, but never of the other alkaloids. All the bases of quebracho produce in frogs direct paralysis of the striped muscles; in mammalia, however, a direct influence on muscular irritability could not be proved. In frogs, the heart also participates in the general paralysis of the striped muscles, which is likely to be preceded by paralysis of its motor ganglia. The arrest of the action of the heart, however, in every instance takes place after complete cessation of the respiration; in mammalia, this effect on the action of the heart is less striking. Of all these alkaloids, quebrachine is the most powerful in its effects, next to it ranks aspidosamine, whilst aspidospermine is the weakest. Although the emetic properties of aspidosamine somewhat resemble those of apomorphia, their dissimilarities are of the greatest importance in their therapeutic bearing. A subcutaneous injection of apomorphia is a less energetic emetic, but it acts as a most violent irritant on some portions of the brain, and especially on the respiratory centres. The greatest therapeutic value of quebracho bark consists in its property of reducing the irritability of the respiratory centre. It will prove beneficial in cases of dyspnœa not depending on impeded aëration—*i.e.*, on insufficient oxidation of the blood in the lungs, and not being a mere compensatory symptom; namely, in dyspnœa, in consequence of disorders of circulation and of diseases of the heart. In other cases, in which the dyspnœa constitutes a purely compensatory manifestation, any attempt at lessening the irritability of the respiratory centres may, under certain circumstances, be fraught with danger, although this remedy may even then occasionally assist in alleviating this distressing symptom. This effect is produced by all the alkaloids of the bark; but quebrachine and aspidosamine deserve the preference, especially the first, the emetic action of a subcutaneous injection of which acts most speedily and energetically. Hydrochlorate of quebrachine is given both internally and subcutaneously in doses from five-sixths of a grain to one grain and a half.

Hiccough Cured by the Extraction of Nine Needles from the Epigastrium.—Liégeois has described in the *Revue Méd. de l'Est* (January 4, 1885) a case of intractable hiccough in a nervous woman, aged twenty-one. The paroxysm lasted twenty-four days, and was so violent that the whole body was shaken, and the noise could be heard at a distance of forty yards. Bromide of potassium and ether had been given without success. Chloral and hyoscyamine produced a temporary improvement, but the paroxysms reappeared after a time. Opium and atropia were then administered, and the hiccough ceased for about a month, when a new attack occurred. Five months later, a small abscess formed in the epigastric region, and a needle, which projected through the skin, was extracted by the patient's sister. An incision was then made by Dr. Liégeois, who found eight other needles in the subcutaneous tissue. This operation was followed by a complete cure, but the author is unable to state whether the needles had been swallowed or introduced under the skin by the patient herself.

The Tendon Reflex in Glycosuria.—Professor S. Rosenstein has made a number of observations concerning the condition of the patellar tendon reflex in cases of diabetes mellitus, from a study of which he comes to the following conclusions (*Allgemeine Medicinische Central-Zeitung*, No. 28, 1885): 1. In a certain number of cases of glycosuria the patellar reflex is permanently abolished, and is not restored, as happens in chronic alcoholism, by the subcutaneous use of strychnine. 2. The abolition of the reflex does not depend upon relative proportion of sugar, or of acetone, nor upon the presence of substances in the urine reducible by the chloride of iron test; and it cannot, therefore, be regarded as a toxic symptom. 3. It is likewise independent of the general nutritive conditions of the body and of the patient's strength, and cannot therefore be due to weakness. 4. The disturbance of the reflex process between the crural nerve and the lumbar cord is, as far as can be determined by one autopsy, purely functional, and is not due to any organic change in the cord. As regards the prognostic value of this symptom, the author does not agree with Bouchard, that it is of very grave import. He also regards it as of slight diagnostic value in comatose conditions, as he has found the patellar reflex absent in uræmic as well as in diabetic coma.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 11, 1885.

THE PROPOSED INTERNATIONAL MEDICAL CONGRESS.

FROM any point the present prospects of a successful International Medical Congress in 1887 are discouraging. It is true that the appointment and action of the New Orleans Committee have been accepted as technically correct, and their revision of the preliminary organization has been promulgated. So far the skies have been cleared and progress has been made. But this progress has only led into further difficulties. For, though the new committee have met and done the work of decapitation and redistribution laid out for them, they have in so doing already created so much bitterness and opposition as seriously to raise the question whether all their efforts at securing international co-operation will not be paralyzed.

In considering the basis of this opposition, the existence of which is so regrettable, two facts stand broadly out, viz.—that the Congress had been satisfactorily and legally organized, and was progressing smoothly, and that then certain men stepped in, not all with motives above suspicion, and instigated the changes resulting in the present troubles. These changes introduced questions of medical politics and geography, of no international or scientific interest, and involved the removal and humiliation of some of the best and most representative physicians in this and other States. It is natural that some feeling is created, while the general verdict can not but be that the action was most unwise.

The justice of the introduction of the question of geography will bear discussion. The East would, we believe, have cheerfully conceded all that was desired; but the introduction of the dead and wearisome Code issue was a most deplorable and irretrievable mistake, a mistake begotten of cretinous prejudice and of a stupid, short-sighted provincialism, which it is painful to have to confess the existence of in our country and profession. This action of the Association can be justified by no reason or argument, and the superlative folly of it is quite beyond the reach of adequate characterization. The only plea put forward is that of a ridiculous and irrelevant "consistency"—a consistency of which the great philosopher of Concord must have had some prophetic inkling when he wrote: "A foolish regard for consistency is the hobgoblin of little minds." All this exhibition of obtuseness and folly is the more exasperating to those who, as we have done, have sincerely desired the success of the Congress, and on this ground alone have wished that politics should be left out.

But beyond all these questions it seems that the treatment of the original committee and its work has caused the withdrawal of many of the best men of Philadelphia, including some prominent officers of the Congress. We regret to learn, also, that the example in Philadelphia will probably be followed in other cities.

Notwithstanding these dark clouds upon the horizon, we might expect little actually to come from them, were it not for the unfortunate fact that it is so much easier to prevent a Congress from being international than to make it so. Our foreign colleagues can only come here in any event at much trouble and expense. They will not come if there is a split and a quarrel, more especially if they see that this takes away from the meetings many of the men whom they would most like to see. They care nothing about squabbles over medical etiquette, and will be disgusted, we fear, to learn that such a thing has been introduced into a scientific body, in order that a few gentlemen who "run" the American Medical Association may be "consistent."

The facts, then, are that there has sprung up a serious and aggressive opposition to the present organization and policy of management of the International Medical Congress; and the matter comes to this: Will these gentlemen who have been thrust aside by the new committee be persuaded to submit peacefully and patriotically to a rule which they do not respect, and join hands to make a successful Congress? Or can not some concessions and compromises yet be made?

Certainly, unless one of these things is done, the international as well as the national character of the Congress is seriously endangered. We earnestly trust that matters may not be driven to an extreme issue, and that some arrangement for securing harmony may yet be perfected.

THE FAILURE OF CIVIL SERVICE IN MEDICAL APPOINTMENTS.

POLITICS has been defined as "the science of putting the ins out and the outs in." Its laws have never been very clearly differentiated, and they have of late received a new disturbing factor in the shape of Civil Service reform. This subject is now occupying the minds of men, of the politician especially. The daily press has teemed with articles on the relations of this reform to the various classes of the community, except to the medical profession. Certain recent developments have raised the query as to what these latter relations really are. We refer to the recent appointment of sanitary inspectors for the summer corps of the Health Board.

Early in February an examination was held for medical positions under the City Government. Thirty-nine men competed, and of these twenty-eight received the seventy per cent. required for passing. In this examination due regard was paid to previous experience in medical work, and to the ability of candidates in speaking French and German (see THE MEDICAL RECORD, February 28, 1885). The criticism was made that the questions upon medical topics were in many instances unpractical. This criticism could not, however, be brought against the questions given in a second examina-

tion held early in June. In this second examination about one hundred and ten competed and eighty passed, but of this number one half stood as low as seventy-five per cent., or only five per cent above the minimum allowed. Thus, altogether, one hundred and eight men had met the requirements of the Civil Service examiners, and their names were sent to the Health Board. At this juncture, however, and in the hands of the latter authorities, the spirit of Civil Service reform experienced a sudden check.

In our former article, above referred to, it was stated that the "weak point of the present system in this city is that when openings occur in any department, the three highest on the list are sent in for each vacancy, but the appointing power is not obliged to select from this number, and can have repeated names sent in, in classes of three, until a selection is made. In this way it is possible for any one standing quite low on the list, but having strong political influence, to obtain an office." This weakness has been glaringly illustrated in the appointment of the corps for the present summer. That the gentlemen chosen passed the examination no one can deny. That they will perform their duties faithfully there is no reason to doubt; but they were not chosen in accordance with the spirit of Civil Service. They were not, in the great majority of cases, those who had most ably responded to the test of the Civil Service examiners themselves. The City Government made a standard, and then repudiated it.

In the second list, with eighty names, the man ranking first was passed over; the man ranking seventy-sixth was chosen, simply because he had stronger political backing. Other instances were just as flagrant. It may be said that several of the successful men had had previous experience on the corps. Presumably this experience was credited to them, and yet even with this prestige they were not, in the opinion of the examiner himself, qualified to head the list.

This is not the spirit of our Civil Service laws. It is simply a perpetuation of the old "influence" system under a different phase. The appointments were in many instances the payment of political debts to those signing the credentials. It was frankly stated at the office of the Health Department that the Board rarely considered a man's examination standing, and that his appointment depended on the amount of "pressure" he could bring to bear upon those in power. This admission is at least frank, and shows just what estimate the Health authorities place upon the present Civil Service law. The statements we have made are facts. They can be verified by inspecting the official records of the city. With no disrespect to the gentlemen whose political backing has allowed them to crowd out those who better responded to the required test, we characterize the present Civil Service of the Health Board as a broad farce.

IMPROPER ADMINISTRATION OF OPIUM.

Considering that nearly all the drugs of the Pharmacopœia which in small doses are capable of producing beneficent results, are, in large doses, capable of destroying life; and considering, also, the amount of medicine-prescribing and medicine-taking which daily takes place in the United States, discriminate and indiscriminate, it is really a marvel that a greater number of serious mishaps do not occur.

It is exceedingly rare for a physician to be brought to the bar of justice to answer the charge of manslaughter because he has carelessly administered a fatal dose of morphine to a patient; but could those physicians who have rendered their patients victims to the living death of an opium-eater be summoned to answer this serious charge, there would be a large assembly. In this array the number of country physicians would not be small. The mischief done by these men is seldom realized by themselves. The enormity of their unconscious guilt is more often manifest to city physicians, hospital and other, whose wide reputation brings the rural sufferers to them, as the last resort, for relief. It is then too often found that the remedy has proved worse than the disease, and that morphine and opium pains are what are making the patient wretched; and the cure depends upon the possibility of curing the opium habit.

The temptation of the country physician to give opium in some form is very great. His patients are scattered over a wide territory. The only visit he can make in the day must be one which will bring relief, sure and speedy, to his patient. He has no time to try if less potent medicines will prove of avail; therefore he prescribes opium.

In some instances the physician himself is a slave to the insinuating drug, and prescribes it to his patients, prompted by that feeling which opium begets of liking to share its pleasures.

Another class of physicians who administer opium are those young in the profession, who wish to impress their clients with their power and skill by producing prompt results.

Could a strict justice overtake those physicians who, by an uncalled-for use of opium, introduce to the dreadful habit those who are made slaves for life, a burden to themselves and friends, it would possibly bring about a state of affairs in which such an event would be of as rare an occurrence as the administration of a promptly fatal dose. Unfortunately we can see no way in which this can be brought about.

SUCCESSFUL TREATMENT OF HAY FEVER.[1]

If a successful treatment of hay fever has been discovered it will be a great boon to those weeping, wheezing, afflicted sufferers, who in the time of roses and new-mown hay, or when the pollen of insignificant weeds pervades the air, are obliged to travel to certain regions to find relief.

These unhappy individuals, according to Dr. Sajous, possess "as a result of heredity or of diseases implicating markedly the nervous system, nerve-centres which have become abnormally sensitive and are therefore inordinately influenced by the external elements to which they respond."

As a result of local disease the nasal mucous membrane becomes hyperæsthetic and transmits to the abnormally sensitive nerve-centres the impressions made

[1] Hay Fever and its Successful Treatment. By Charles E. Sajous, M.D. Philadelphia: F. A. Davis, Publisher. 1885.

by the "external elements" (pollen, etc.), which results in a paroxysm of "hay fever."

These are the three conditions necessary for a paroxysm, and when one is absent, as is the case with the external visitants a portion of the year, and all the year in certain regions, it will not take place. Hence to cure the disease is to render the hyperæsthetic nasal membrane oblivious to the annual visitation of the external cause. The writer maintains that this can be done by cauterizing the hyperæsthetic portions of the nasal membrane, which he has accomplished with pleasing and permanent results by means of the galvano-cautery or acids.

He describes these hyperæsthetic areas as consisting of three—posterior, middle, and anterior. The posterior area is implicated when reflex asthma is the most prominent symptom; the anterior when the head symptoms alone are present; the middle is the starting-point of all the symptoms combined.

He recommends that abnormal conditions of the nasal cavities, such as hypertrophies, polypi, exostoses, etc., be eradicated before using the superficial cauterization. The best results are obtained by instituting treatment six weeks at least before the onset of a paroxysm, though it may be conducted during a paroxysm resulting sometimes in an arrest of it or a beneficial modification. Immunity depends on the thoroughness with which the treatment is conducted.

It would seem from the perusal of Dr. Sajous' monograph on the subject that the hay fever might become unknown, provided its victims would put their hyperæsthetic nasal membranes under the treatment of an adept in rhinology. The banishment of hay fever from the list of diseases would be a boon to all except the hotel-keepers of those resorts where, since the "external irritant" does not lurk in the atmosphere, the cause is removed and a cure is effected.

With the mechanism of the disease still in mind there remains one other method, which will be as much superior to that advanced by Dr. Sajous, as his is better than the now prevailing method of changing abode, namely, that of finding a remedy which will act directly upon the abnormally sensitive nerve-centres. We commend this to investigators.

SIR SPENCER WELLS AND OVARIOTOMY.

Exception has been taken by a Western journal to what was said in a recent Record editorial concerning the relation of Sir Spencer Wells to the revival of ovariotomy. The claim is made that to Washington L. Atlee, of Pennsylvania, is due the position which the English surgeon has "arrogated."

The history of nearly all surgical operations emphasizes the fact that they are rarely the product of the genius of any one man. Each age, dating back to the birth of medical literature, with its consequent dissemination of ideas, has suggested some valuable theory which later times have put in practice. The process has been one of evolution. In many directions the highest type has not yet been reached. Perhaps no operation more clearly illustrates this idea than that of ovariotomy. Nearly two hundred years ago it began to be seriously talked of, but after a century and a half it still had many more enemies than friends. During this period isolated contributions were made concerning our knowledge in "condition, indication, and operative technique." Men were at work in England, and later in America, each generation profiting by the experience of its predecessor, and advances were made step by step toward the goal of demonstration. In the category of contributors toward this end, both Atlee and Wells occupy enviable positions. The impulse given to the development of the operation by the Atlee brothers is very justly, we think, ascribed by Dr. Emmet (last edition) to Dr. Charles Clay, of Manchester. The statement of Carl Braun, that "Atlee performed the operation two hundred and forty-six times from 1843 to 1871, and by this has contributed the most to its enfranchisement," is simply a begging of the question. To "enfranchise" anything is, according to Webster, to liberate it from slavery. When Wells began to operate in 1858, ovariotomy was most emphatically under the yoke. That he profited by the publication of Atlee's cases in 1855 is doubtless true. By 1872 he had completed his first five hundred cases, or more than twice as many as Atlee, in three years' less time. If figures are to be the criterion, the case needs no further argument. The tone of medical literature in 1858 was decidedly against the operation, but Wells by his splendid and increasing successes speedily brought the cause to a triumphant issue.

THE ACTUAL DEATH-RATE OF WAR.

Some tables have recently been published, based upon a report of the Adjutant-General of the United States Army, showing the actual per cent. of deaths from sickness and by battle during the War of the Rebellion. It is a truism that in war disease kills more than the bullet. The detailed facts showing this, however, in the case of our own war, are of special interest.

The States and Territories contributed to the army of the Union 3,500,000 men. Of these, during the four years of war, there were killed in action 67,030, or 2.88 per cent.; there died of wounds 43,000, or 1.85 per cent., making a total of deaths from violence 110,030, or 4.73 per cent. On the other hand there died from disease 224,586, or 9.68 per cent., disease being thus twice as fatal as the bullet.

The total mortality among Union soldiers during the war would be 334,616, or 14.41 per hundred of those engaged. Thus over fourteen out of every hundred soldiers died in the four years' war.

This is an enormous death-rate, but the figures are often wrongly used, and they do not accurately indicate the mortality rightly attributable to the war. The ordinary death-rate among male adults is about nine per thousand annually in this country. During the four years of the war there would have occurred under any circumstances among the three and a half million of soldiers about 126,000 deaths, leaving, therefore, only somewhat over two hundred thousand deaths attributable to the war. To put it in a general way, instead of four men who would have died in the natural course of events, fifteen men out of every hundred died in the course of the war.

The death-rate from bullets is only a little greater than the death-rate in civil life, but the soldier has added the enormous risks from disease.

A CONTRIBUTION TO PULMONARY SURGERY.

It is not so very long ago that diseases of the internal organs, both abdominal and thoracic, were looked upon as exclusively within the domain of the physician. They were to be relieved, if possible, by medical means, but if these failed, as they often did, there was no recourse left to the patient but to settle up his earthly affairs as best he could and resign himself to the inevitable. But the present generation has seen great changes in this respect. We are no longer content to stand by with folded arms and watch the gradual destruction of any organ by disease, but the surgeon steps in, and with his knife cuts out the offending part, with as little hesitancy as he formerly amputated a diseased limb. Having conquered the field of abdominal surgery, we now turn to the thoracic organs. The distended pericardium is tapped, and even pulmonary cavities are entered with the needle, and their fetid contents removed. Experiments have also been made on animals to determine how much of the lung itself could be cut away without destroying life.

A further contribution to pulmonary surgery was made at a recent meeting of the London Clinical Society, an account of which we have received from our London correspondent. At this meeting, Dr. Cayley, who has already done much to advance surgery of the lungs, related a case of hæmoptysis, in which he had artificially induced pneumothorax, so as to collapse the lung, and thus arrest the hemorrhage. The patient was a porter, twenty-one years of age, who was admitted into the Middlesex Hospital, on February 9th, for hæmoptysis. During the next four or five weeks he had repeated attacks of severe hemorrhage, despite active treatment. There were no well-marked physical signs of pulmonary disease, and Dr. Cayley thought the hemorrhage was due to a pulmonary aneurism, or to the ulceration of a large vessel. He determined to induce pneumothorax, with the expectation that the great diminution of the circulation through the collapsed lung, together with the pressure exercised by the air, would arrest the hemorrhage. And if it should be subsequently found that there was active development of tubercle in progress in the lung, no harm would have been done, and it might even be checked for a time. The pleural cavity was accordingly opened on March 10th, by Mr. Hulke, and a double drainage-tube introduced. Carbolic gauze was placed over the opening, and air passed in and out freely. The breathing was greatly accelerated, and the apex of the heart was moved over to the right. The patient coughed up blood twice during the night following the operation, but there was no more hemorrhage after this. He died suddenly on the fifth day after the operation. At the autopsy both lungs were found studded with recent gray miliary tubercles. The right lung was free from any old tubercular disease. In the apex of the left lung there was a very small old vomica. The lower lobe, and part of the upper lobe, were collapsed, and the pleural surfaces smeared with recent lymph. In the lower part of the upper lobe was a cavity as large as a walnut, nearly filled by a light-colored laminated clot. There was a small cavity in the centre of the clot which communicated with a good-sized branch of the pulmonary artery.

The wisdom of this procedure might be questioned by many, yet it would seem in this instance, on the whole, not to have been unjustifiable. For there were no signs of old pulmonary disease during life, and the operation arrested, at least temporarily, the hemorrhage, which was sapping the patient's strength, and threatened to cause his death. Possibly, as was suggested during the discussion of this report, the same result as regards arrest of the hemorrhage might have been obtained by the injection of carbolized air into the thoracic cavity, through the needle of an aspirator, or even of a hypodermic syringe. This experiment will doubtless be repeated, and it may prove, in the end, a valuable means of arresting hæmoptysis, uncontrollable by ordinary medical measures.

News of the Week.

Navy News.—Official List of Changes in the Medical Corps of the U. S. Navy during the Week ending July 4, 1885: Assistant Surgeon Joseph Shofer, assigned for duty on board U. S. Receiving Ship St. Louis, League Island, Pa., July 10, 1885.

College of Physicians and Surgeons of Chicago.—Dr. N. Senn, of Milwaukee, Wis., has accepted the Chair of Principles and Practice of Surgery, and Professor Christian Fenger that of Clinical Surgery in the College of Physicians and Surgeons of Chicago.

New York Post-Graduate School.—Dr. Horace T. Hanks has been elected Professor of Diseases of Women, in the New York Post-Graduate Medical School and Hospital. Dr. Lewis S. Pilcher has been elected Professor of Clinical Surgery in the same school.

The Medical Register for 1885-86.—The twenty-third volume of the "Medical Register" of New York, New Jersey, and Connecticut comes to us promptly in its usual style. It contains the names of 6,545 physicians, as follows: New York State list, 2,775; New Jersey State list, 756; Connecticut State list, 514, an increase of 89, 18, and 18 respectively, or a total of 125. The New York City list comprises 1,902 names, an increase of 113. The Brooklyn list contains 598 names, 87 more than last year. Total increase in the three States, 325. Of those registered in the New York City list last year 316 have changed their residences in the city, and 26 have died. There are now 142 serving in the different hospitals and asylums.

Graves' Disease in Blondes.—Dr. George C. Mosher, of Kansas City, writes: "Dr. Neal's query in No. 25, vol. xxvii., of The Medical Record, calls to mind five cases of Graves' disease which I have seen, two in Ohio and three here, all occurring in female subjects. Each of these persons had blond hair. The coincidence, if nothing more, is striking."

The Dublin Medical School.—A sum of from $50,000 to $60,000 is about to be expended in adding to the buildings of the Dublin University Medical School, which, owing to the steady increase of the school in recent years, are no longer adequate for its accommodation.

A Novel Review and Criticism.—For a picturesque evacuation of rubbish commend us to an editorial review of "An Ethical Symposium" in a recent issue of the *New England Medical Monthly*. Our usually amiable and progressive contemporary is not only two years behind time in its wholesale denunciations of some very honorable and clear-sighted gentlemen, for "appealing to the public," but it quite forgets that a similar work to the "Ethical Symposium," appealing to just as wide a circle, was first issued by one of its own *dei majores*. In the name of the Prophet, dear contemporary, let us have peace.

The *New Orleans Medical and Surgical Journal* comes to us in a new dress and improved make-up, highly creditable to its present energetic editors.

Collective Investigation in Russia.—A meeting of delegates from the different medical societies has been held in the Red Cross Hall, in St. Petersburg, for the purpose of organizing collective investigation in Russia. The question arose as to whether it would be better to establish an independent central committee in Russia, or to send the individual reports direct to the International Committee in London. The meeting unanimously decided in favor of the former alternative, on account of the difficulty of entering into an extensive correspondence in a foreign language. The meeting consequently resolved itself into the Collective Investigation Committee for Russia, and arranged to keep up communication with the English Committee.

Further Withdrawals from the Organization of the Congress.—We learn that at a meeting of the Boston officers of the International Medical Congress, resolutions to withdraw from the organization of the said Congress were adopted. Drs. R. Amory, C. J. Blake, H. I. Bowditch, James R. Chadwick, Derby, Wadsworth, and, in fact, all the officers, are included in this movement. It is also stated that Drs. S. C. Busey, Swan, Burnett, and other Washington physicians; Dr. J. N. Mackenzie, of Baltimore, and Dr. George J. Engelmann, of St. Louis, have withdrawn.

A Practical Attempt at Reform in Medical Charity.—The Northeastern Dispensary, of this city, which is earning an excellent reputation for liberality in management, has undertaken to carry out a practical measure of reform with regard to the dispensing its charity. The following circular has been drawn up, signed by every member of the medical staff, and forwarded to the managers, who, we understand, have heartily approved of it: "We, the undersigned, Attending Physicians to the Northeastern Dispensary, feeling the great evil resulting to medical charity throughout our city from neglect of the use of proper means to rid our institutions of charity from those able to pay, and other unworthy applicants for gratuitous service, and feeling that we, as a class, have placed at our disposal means intended only to relieve the *worthy poor*, feel called upon to request, that on and after September 1, 1885, the Northeastern Dispensary co-operate with the Charity Organization Society in the work of compelling this nuisance to cease, assisting in avoiding the abuse of medical charity throughout our city."

Vacancies Left in the Organization of the International Medical Congress by the Withdrawal of the Philadelphia Members.—The withdrawal of the Philadelphia physicians from any connection with the International Congress, leaves some important official vacancies in the revised preliminary organization. The office of Secretary-General has been made vacant by the withdrawal of Dr. John H. Packard; the Presidency of the Sections on Therapeutics, Medicine, and Anatomy, are made vacant by the withdrawal of Drs. H. C. Wood, J. M. Da Costa, and J. Leidy; Vice-Presidents of the Sections on Pathology, Medicine, Surgery, Obstetrics, Ophthalmology, Dermatology, and one Vice-President of the Congress, Dr. Alfred Stillé, have withdrawn. The Secretary of the Section on Therapeutics, and three members of the Committee of Arrangements have withdrawn. Philadelphia is left practically unrepresented in the organization of the Congress. Out of forty-eight officers twenty-eight have withdrawn, and these include nearly all who held prominent positions. The resignation of Dr. David W. Yandell leaves vacant the Presidency of the Section on Surgery. Thus, four of the most important sections are left headless.

The Representation of New York City in the International Congress.—Only twenty-nine physicians of this city, nearly half of whom are connected with the same medical college, occupy official positions in the preliminary organization of the proposed Congress. Philadelphia, with fewer physicians, was given forty-eight positions, and Boston, with one-fourth the number of doctors, was given twenty positions.

One was Taken and the Other Left.—

The Canada Medical Association holds its annual meeting at Chatham, Ont., September 2d and 3d, under the presidency of Dr. Osler.

A New Cancer Cure.—Dr. Pampilo, surgeon of St. Peter's Hospital, Pernambuco, cites many cases in which he has cured cancers, chancroids, epitheliomas, and malignant erectile tumors by the use of the Piscidea erithrina juice, etc.—*Progr. Med., Cincinnati Lancet and Clinic.*

The Deterioration of Chrysophanic Acid.—The editor of the *Journal of Cutaneous and Venereal Diseases* calls attention to the fact that chrysarobin (chrysophanic acid) has much deteriorated in quality in the past few years, so that ten per cent. solutions do not accomplish now what five per cent. solutions used to do.

The New Army Medical Museum.—The plans for the new National Medical Museum building will soon be completed by the architects and submitted to the Board of Commissioners for Approval. The Board consists of the Secretary of War, the Secretary of the Smithsonian Institution, and the Architect of the Capitol. The site selected for the structure is the Smithsonian grounds, just east of the National Museum. The original estimate of its cost was $250,000, but Congress appropriated only $200,000, and provided that the completed structure shall not exceed that sum. It will extend three sides of a parallelogram, with a plaza front to the south, and will have between fifteen and eighteen thousand square feet of space upon a single level. The ground floor is to be used for the pension records of the War Department.

A New Brazilian Journal.—We have received the first number of a new Brazilian Medical Journal, entitled *Revista dos Cursos Praticos e Theoricos*. It is the official organ of the Faculty of Medicine of Rio Janeiro, and is edited by five professors of that Faculty. The present issue contains a number of carefully prepared articles.

The late Dr. John F. Gray, of this city, a well-known homœopathist, used to prescribe stibium so often that he once said he expected to have inscribed on his tombstone, "John F. Gray, Stibium." Stibium is a good old remedy, much used in the days of Paracelsus and the chemical school. Dr. G. used it in physiological doses.

Proposed Medical Legislation in Georgia.—The Medical Association of the State of Georgia, says the *Atlanta Medical and Surgical Journal*, has raised a committee to call the attention of the General Assembly to, and invoke its action on, two subjects of interest to the medical profession. Bills in relation to them have been introduced, referred to appropriate committees, favorably reported on, and are now pending before that body. The object of one of them is to provide for the payment of reasonable compensation to witnesses sworn as experts in judicial trials; the other, to facilitate the study of anatomy, by permitting, under proper instructions, the procurement of the necessary material for that purpose.

Consultations with Homœopaths in Canada.—The *Canadian Practitioner* complains that several prominent physicians in the Province consult habitually with homœopaths. It very correctly deplores this practice, but incorrectly urges the Dominion Association to take action in the matter. Any attempt on the part of a body of physicians to combine and try to take away the right of the individual to consult with whom he pleases will fail in the future, as it has done in the past. The best way to get rid of homœopaths is to show the people that rational medicine is the best, and includes all the good in homœopathy or any other "pathy."

The Cholera in Spain.—In the past fortnight the spread of cholera in Spain has been extraordinarily rapid. Up to the last week in June about 4,000 cases had been reported. Since then the total number of cases has reached the neighborhood of 15,000. Every day the papers report a total number of new cases ranging between one and two thousand. The mortality, if correctly given, is somewhat less than one-half, and does not differ greatly from that of last year's epidemics. But it will be seen that already the epidemic in Spain has had more victims than that of last year in France. As this result has been reached so early in the summer the outlook is a bad one.

A New City Hospital for Contagious Diseases will shortly be opened, under the direction of the Health Department, on North Brothers Island. It is intended to take the place of the Riverside Hospital. The hospital building is of brick, two stories high, heated and ventilated with the most improved appliances. There is a large ward on each floor, lighted on three sides, and overlooking each ward is a small glass-incased room to be occupied by nurses when their actual attendance in the sick-room is not required. The hospital is designed to hold seventy-five patients. The plans call for ten additional frame buildings, capable of holding forty people each, to be used in case of an epidemic, but only three of these will be built at present.

Reviews and Notices.

Intestinal Obstruction: Its Varieties, with their Pathology, Diagnosis, and Treatment. By Fred. Treves, F.R.C.S., Surgeon to, and Lecturer on Anatomy at, the London Hospital, Hunterian Professor of Anatomy at the Royal College of Surgeons of England. With Sixty Illustrations. Philadelphia: Henry C. Lea's Son & Co.

This work is in substance the essay to which the Jacksonian Prize for 1883 was awarded by the Royal College of Surgeons of England. It is a thoughtful and well-written monograph on a subject that interests both the physician and surgeon. Dr. Treves has classified the various forms of intestinal obstruction according to pathological data, because, as he truthfully remarks, our clinical knowledge of the subject is less precise than our knowledge of the morbid anatomy of intestinal obstruction. The work is illustrated by some well-executed original drawings, and is altogether worthy of being read and studied.

A Manual of the Practice of Surgery. By Thomas Bryant, F.R.C.S. With Seven Hundred and Twenty-seven Illustrations. Fourth Edition, thoroughly Revised. Pp. 1039. Philadelphia: Henry C. Lea's Son & Co. 1885.

The present edition of Bryant's "Surgery" has been very thoroughly revised by so competent a surgeon and literary critic as Dr. John B. Roberts. It shows many marks of improvement over earlier editions, and in size and typography it is quite the model for a student's and practitioner's manual. Mr. Bryant's work has gone through three American editions, and it is familiar to American readers. The author is a skilful surgeon of long experience, and his work is clear and practical in its character. Mr. Bryant is anti-Listerian in his views, and the fact that there is now a fashion for antiseptics has, perhaps, lessened the prestige of his work. We believe that Mr. Bryant is probably as successful a surgeon as any of the ultra-Listerians, yet he has unquestionably erred in exhibiting a certain amount of prejudice against the antiseptic methods; for, whatever may be the theory, nothing is more certain than that the young surgeon should be emphatically taught the value of antiseptic cleanliness in its most minute details. This Mr. Bryant does not do.

We do not propose to go into any analysis of the work before us. Bearing in mind the criticism that has been made, the book can be safely trusted to guide the student and practitioner.

A Treatise on the Science and Practice of Midwifery. By W. S. Playfair, M.D. Fourth American Edition, from the Fifth English Edition, with Notes and Additions, by Robert P. Harris, M.D. Philadelphia: Lea Brothers & Co. 1885.

In the preface to the first edition of this work, in 1876, the author states "that there is no department of medicine in which more has been done of late years, and none in which modern views of practice differ more widely from those prevalent only a short time ago." In the last decade this cannot be said with as much truth. Consequently this edition contains few striking changes, and these naturally occur in that department in which at present investigation is most rife, namely, embryology.

The work is regarded by teachers in obstetrics, from the conciseness of its statements of theories, and its clearness, as one of the best for students, and it will probably maintain its position for some time to come among the standard works on the subject of which it treats.

A Treatise on Asiatic Cholera. Edited and prepared by Edward Charles Wendt, M.D., Curator and Pathologist of St. Francis' Hospital, New York Infant Asylum, etc. 8vo, pp. 403. New York: William Wood & Co. 1885.

We have nothing but praise for the careful and painstaking work of Dr. Wendt, in this the most complete volume on the subject of cholera that has appeared on this side of the water. His associates are those best qualified to write on their respective topics. The work is divided into seven parts. Part I. treats of the "History of Asiatic Cholera." Section I. is by Dr. John C. Peters, of New York, on the "General History of the Disease, and the Principal Epidemics up to 1885." Dr. Ely McClellan writes Section II., giving a "History of Epidemic Cholera as it affected the Army of the United States."

Dr. Wendt's work, proper, begins with Part II., concerning etiology. Successive parts treat in turn of symptomatology, course, duration, mortality, complications, and sequelæ. The chapters on morbid anatomy and pathological histology are full and complete. Part V. gives a full account of the methods of bacterioscopy and the preparation of pure cultures. Treatment is discussed in Part VII.

Part VI. is divided into three sections. The first, by Dr. George M. Sternberg, U.S.A., is on the "Destruction of the Cholera Germs." The second, by Dr. John B. Hamilton, Surgeon-General United States Marine Hospital Service, concerns the "Prevention of the Spread of Cholera." The third, by Dr. McClellan, is on "Cholera Hygiene as Applied to Military Life."

It will be seen that while the scope of the work is a wide one, no more able corps of *collaborateurs* could have been associated in its preparation. The early history of cholera in New York is treated of in full by Dr. Peters, and is the most complete *résumé* of the subject yet published. A wide range of discussion is taken by the other associate editors concerning international and municipal sanitation. It is about Dr. Wendt's part of the work, however, that public interest will most centre. He discusses the various etiological theories of the last half century, dwelling particularly on that of Koch. A translation is given in full of the latter's memorable address before the Berlin Conference last summer. In regard to Koch's doctrine, Dr. Wendt takes the middle ground, that "while it has not been finally established as a scientific truth, it has much in its favor." He truly says that "the extremely divergent opinions regarding cholera, entertained even at the present day, would scarcely justify an attempt to present a completely harmonious picture of the disease." His conclusions are as follows: Cholera originates in India, where it is now endemic. Its specific cause is an organized body capable of rapid multiplication both within and without the human organism. Any extension of the disease is caused solely by human intercourse. It never originates *de novo* in a given locality. Its outbreak and dissemination may be favored by local conditions. Such dissemination may occur from direct personal contagion, but far more frequently by fomites and water-channels (rivers, pipes, sewers); exceptionally by air, but only at very short distances. The virus acts first and with greatest intensity upon the intestinal tract.

Dr. Wendt does not think we possess any specific cure for the disease, yet he earnestly deprecates any resignation to the idea that we cannot control the disease by treatment. We should promptly control every premonitory diarrhœa with the opium tinctures and mineral acids (preferably sulphuric). Complete rest and abstinence from food should be enjoined. If the disease develops into well-marked cholera, he recommends before collapse morphine hypodermatically, with iced fluids, weakly acidulated, for thirst. In incipient collapse a warm bath by means of slaked lime is deemed of service. In well-marked collapse all medication should be stopped. During reaction careful nursing and strict diet are all important. Solid food is dangerous. Opium should be avoided, as a rule, in this stage. Then gradually build up the system. Ferrán's inoculation experiments Dr. Wendt does not regard, as yet, as by any means decisive.

Robert Boyle: A Biographical Sketch. By Laurence Saunders. Pp. 104. London: Gilbert Wood & Co. 1885.

The name of Boyle was borne by two Englishmen, father and son, whose chief aim was to establish a scientific system of ventilation for large buildings and for vessels. In the literature of sanitation their work has been fully recognized. This biographical sketch is well written, and highly extols Boyle as an inventor and philanthropist.

The Regimen in Gout. By William Ebstein, Professor of Clinical Medicine in Göttingen. Translated by John Scott, M.A., M.B., Honorary Physician, Manchester Hospital, etc. 8mo, pp. 64. London: J. & A. Churchill. 1885.

Many practical suggestions are contained in this small volume. The author has no particular hobby, and advises moderation in all things, without inclining at all to the starvation plan. All gouty manifestations he regards as due to uric acid, which is a "chemical poison which can cause not merely inflammatory but also necrotizing and necrotic processes in animal tissues." Animal and vegetable diet are permissible. Fat is regarded by Ebstein as a valuable food in gout, within necessary bounds. Alcoholic drinks may be used in moderation. The intestines should be irritated as little as possible. Baths are valuable, the warm bath being generally preferable in cases with renal complications.

The Diaphragm and its Functions: Considered Specially in its Relations to Respiration and the Production of Voice. By J. M. W. Kitchen, M.D. "The Voice" First Prize Essay. Albany: Edgar S. Werner. 1885.

This little treatise calls attention in a forcible way to the often overlooked importance of the diaphragm in the human economy. It is, however, of greater value to professional singers than to the practitioner, who is supposed to be familiar with the evils of tight-lacing and similar offences against the chief respiratory muscle of the body.

Reports of Societies.

KENTUCKY STATE MEDICAL SOCIETY.

Thirtieth Annual Session, held at Crab Orchard Springs, Ky., June 4, 5, and 6, 1885.

(Special Report for THE MEDICAL RECORD.)

FIRST DAY—WEDNESDAY, JUNE 4TH—AFTERNOON SESSION.

THE thirtieth annual session of the Kentucky State Medical Society was called to order at Crab Orchard Springs on Wednesday afternoon, June 24th, by the President, Dr. Pinckney Thompson, of Henderson.

Prayer was offered by the REV. J. BOGLER, of the Presbyterian Church of Hustonville.

COLONEL W. S. HAYES, of the *Louisville Courier-Journal*, President of the Crab Orchard Springs Co., delivered the address of welcome, which was supplemented by one from Dr. EDWARD ALCORN, of Hustonville, Chairman of the Committee of Arrangements.

DR. WM. BAILEY, of Louisville, delivered the report on the

PRACTICE OF MEDICINE.

He thought the common practice of encumbering the office table of the practitioner with new preparations in pharmacy had grown to be a great nuisance. He had not the courage to undertake to uncork the one tithe. He thought the physician should go before and ask the pharmacist to prepare such a medicine, not the pharmacist urge the physician to use his preparations. He believed that it called forth too much free medicine taking. He recommended that new remedies be first thoroughly tried by competent hands in public institutions, then given to the profession if found worthy. He discussed cholera and ascribed all honor to the brave men who were investigating it so diligently. The germ-theory of disease is the great question of the age, whether it stands or falls. All conditions in regard to this disease have not been maintained in most cases, and we are compelled to argue solely upon analogy or inference. To prove that the comma bacillus is the cause of cholera it is necessary to find the bacilli in the blood of the patients sick with cholera; that they shall be found in every case; that they shall never be found where the disease does not exist, and that inoculation with them shall produce the disease. Dr. Strauss claims that the shorter and more violent the attack of cholera the fewer were the bacteria found in the intestines. This is an important consideration in determining the causative relation between cholera and "commas." To my mind they should yet be held *sub judice*. I feel like asking you on this account to further make use of your knowledge of punctuation, and after every "comma" (,) to place an interrogation (?), as denoting that further inquiry or investigation is to be made before the period (.) can be reached, and then Eureka (!!!). These investigations can be carried on but by the few favorably situated for study. Therefore we must possess our souls in patience and wait till the conclusion is formed. He thought from the history of cholera that it is due to climatic influences, as malaria, for instance, or epidemic dysentery and yellow fever. Improved sanitation should be the watchword. He inclined to the plausible germ-theory, and stood ready to bow to the inexorable power of logical demonstration.

The report was discussed by Drs. Dudley S. Reynolds, Louisville; J. M. McCormic, Bowling Green; J. B. Marvin, Louisville; and John Jaeger, Campbellsburg.

FIRST DAY—WEDNESDAY, JUNE 4TH—EVENING SESSION.

DR. PINCKNEY THOMPSON, of Henderson, by virtue of his office, delivered the

PRESIDENT'S ADDRESS.

He congratulated the Society on its ability to meet together at such a pleasant place. He paid a beautiful tribute to the dead members. In viewing this gathered assembly he proudly thought, "I, too, am a physician." He spoke of the profit to be gained from such gatherings, all sharing each other's labors and experiences—in fact, a sort of universal clinic. The wealth of wisdom of the wise and the great becomes more or less the actual possession of the humblest member of our profession. We are second to no other class of men in the world. A wise old Roman long since said: "Men are at no time so like the gods as when they try to give health to other men."

He spoke of him who lifted the practice of medicine from a tyrant priesthood and a mercenary craft to an unselfish profession. He who takes upon himself the office of a physician takes upon himself a very grave responsibility. Neglect or abuse must be most culpable. At the door of the physician he laid the responsibility of many of the crimes of the world. For to whom are the feeble constitutions and the defective intellects more chargeable? To have a good brain we must have good blood. "Blood will tell." Whence can blood, physiologically speaking, come to him who has been born and bred in disregard of the laws of health; wanting good blood the brain-power fails. Then the whole life, mental, moral, and physical, fails and falls; degeneration results. He referred to the physical, mental, and intellectual degeneration of American women. "Then like brings forth like: this so-called course of life is a course of death. Who, if not the doctor, can stem this fatal tide." Overpressure at school was considered. He compared the school-children of the city with those of the country. Who of us have not seen again and again the country boy go to the town or city, and with his robust constitution and cranium full of brain-power, ride over his city or town competitors. The women of this have not improved over the former generation. He would like to think each girl an angel, and every woman a goddess. But they would be very sick angels and very feeble goddesses. The city school-houses, which he termed elevated slaughter-houses, came in for their share of condemnation. He referred to the increase of gynecological sanitariums, and said that when a man marries himself to one of these latter-day girls, brought up in a five-story school-house, he mortgages himself to some doctor for the whole time his wife shall live. He lauded the prevention over the cure of disease, and appealed to the profession to do all in its power to mitigate this evil. He thoroughly believed in educating the people, especially the mothers, in the proper care of their daughters.

DR. E. WILLIAMS, of Cincinnati, next read a paper on

THE PHYSICIAN'S OPPORTUNITY FOR BEING AND DOING GOOD.

By physician he did not mean the patent-medicine man or advertising quack. All proprietors or dealers in and advertisers of such so-called medicines will have to face an account at the last day that no physician would be willing to meet. The toot-horn quack has too much brass and cheek for an honest doctor. His brazen pretentions can pass current only with ignorant people. He may make money, but money cannot save him from the bottomless pit, where he will seethe forever in the all-healing vapors of his infallible nostrum. He then defined a good physician. It was not, he said, goody-goodness, which is pious taffy, neither nasal twang righteousness. Modest modesty never whines. He next considered the relations of the minister and physician, saying that they should be co-workers, not antagonists. The following is the prayer of the doubting physician at the death-bed: "O God, if there be a God, have mercy on this man's soul, if he have a soul." No half-way shanty, shaky as this prayer, will answer there. He believed in the need of a sound divinity in the medical profession, and a healthy hygiene in the Church. He denounced the practice of religious periodicals advertising quackery as an outrage on God and man. But what use to denounce when "there's millions in it." Theologically he believed in the germ-theory.

SECOND DAY—THURSDAY, JUNE 5TH—MORNING SESSION.

The Secretary reported $100 contributed to the Sims Memorial Fund. He had received $200 dues; leaving $75.05 in the treasury.

A number of new members were received, among them

TWO LADY PHYSICIANS,

the first of their sex to become members of this Society.

DR. J. M. MATTHEWS, of Louisville, made the report on

GENERAL SURGERY.

He commenced with a tribute to the memory of Samuel D. Gross, who had been at one time president of the Society. He touched mostly on results of new methods in surgery. The scope of the subject being so great, he confined his remarks to those operations of recent attempt. Listerism, if it had but caused greater attention to cleanliness, has done well. Attention to minor details was urged, also climate, sanitation, hygiene, and general surroundings of the patient. Since our last meeting there has been given us a surgical boon second only to ether and chloroform, viz., the hydrochlorate of cocaine. It has a wide range of surgical practice in the eye, ear, nose, mouth, throat, etc. The physiological action seems to be the paralyzation of the sensory nerves, and it may be the posterior columns of the spinal cord. Knapp says that it abolishes reflex irritation, and that it has no cumulative effect and exerts no bad effect on the nutrition of the parts subjected to its action. A question of moment is, Does the application prevent or lessen repair? In some operations done by myself I have imagined that it did. When large amounts of skin are to be cut through I have found that rhigolene applied locally by spray is equal, if not superior, to cocaine. In rectal diseases cocaine is not a success. He then considered general etherization and spoke of the comparative value of different anæsthetics. Rectal etherization has not met with the success that was once hoped for. It now has but few advocates, who can say but little in its favor. He considered antiseptic surgery, speaking of bichloride of mercury, iodoform, hydrate of chloral, bismuth, turf-dressing, boracic acid, eucalyptus oil, aseptol, naphthaline, Listerine, etc.

A question, to the surgeon one of great moment, is, Can he while attending operations of pyæmia, erysipelas, etc., prevent the contagion that is said to be communicable? Here he quoted the views of Professor Volkmann, as written to Dr. George F. French, of Minneapolis, and quoted in a paper by the latter read before the Obstetric Section of the American Medical Association at New Orleans. Volkmann says: "A surgeon who disinfects himself well can, immediately after making a *post-mortem*, undertake any operation known to surgery." This is a strong saying of an eminent man, very hard to believe. He considered abdominal surgery, and deplored the fact that it was not followed with more success under American hands. Lawson Tait says this is due to the fact that too many men are engaged in the work. He queried, Is it not justifiable to make abdominal section for gunshot injury? He considered surgery of the kidneys, nephrotomy, nephro-lithotomy, and nephrectomy; then the surgery with relation to empyema, the thoracoplastic operation of Estlander.

DR. T. A. REAMY, of Cincinnati, in discussing the paper, said: I can conceive that it is perfectly safe to pass from the dead-house to the operating-table. The germs of the dead-house are not those of disease. It is a question of greater importance to determine can one pass from the house of the living to the lying-in chamber? He believed it could be done, and gave minutely his formula for a disinfecting bath.

The paper was further discussed by Drs. E. Williams, of Cincinnati; A. M. Vance, W. O. Roberts, T. B. Scott, and William Cheatham, of Louisville.

DR. ARCHIBALD DIXON, of Henderson, reported on

LAPAROTOMY.

He reported a case of abdominal tumor, believed to be uterine fibroid, and producing ascites.

OFFICERS ELECT.

The Committee on Nominations made the following report, which was adopted, and the gentlemen elected:

President—Dr. J. P. Thomas, Pembroke.

Second Vice-President—Dr. O. D. Sharley, Winchester.

Junior Vice-President—Dr. R. C. McChurn, Lebanon.

Permanent Secretary—Dr. J. Steel Bailey, Stamford.

Assistant Secretary—Dr. F. Dunlap, Danville.

Treasurer—Dr. Edward Alcorn, Stamford.

Librarian—Dr. J. L. Taylor, Warren County.

Chairman of Committee of Arrangements—Dr. S. W. Willis, Winchester.

Winchester was chosen as the next place of meeting; time, the last Wednesday in June.

SECOND DAY—THURSDAY, JUNE 5TH,—AFTERNOON SESSION.

DR. DUDLEY S. REYNOLDS, of Louisville, made the

REPORT ON OPHTHALMOLOGY.

He considered it of great importance to know well the cause of squint and important to correct it as soon as possible. Errors of refraction should be looked after.

The paper was discussed by Drs. E. Williams, Cincinnati; William Cheatham and J. Morrison Ray, Louisville.

DR. WILLIAM CHEATHAM, of Louisville, made the

REPORT ON OTOLOGY.

His paper dealt mostly of earache, its importance and manner of treatment; he warned every one against the use of poultices; and advocated early treatment in all cases.

Discussed by Drs. Webb and Howard, of Shelbyville; Preston B. Scott and William Bailey, of Louisville; E. Williams, of Cincinnati; Pinckney Thompson, of Henderson; J. Jaeger, of Shelbyville; and H. W. Alexander, of Clintonville.

DR. W. O. ROBERTS, of Louisville, read a paper on "Herniotomy," reporting a number of cases.

DR. J. MORRISON RAY, of Louisville, read a paper on "Wounds of the Anterior Segment of the Eyeball."

DR. WILLIAM CHEATHAM, of Louisville, treated of "Neuro-Retinitis Albuminurica," and reported a number of cases and showed microscopical and photographic specimens with the magic-lantern.

DR. J. B. MARVIN, of Louisville, read on "Primary Lateral Sclerosis of the Spinal Cord." Illustrated by the magic-lantern and microscopic and photographic views.

DR. J. P. THOMAS, of Pembroke, made the report on

PHARMACY.

He considered kairin and other antipyretics, pinus canadensis, and hydrastis. He thought there were too many "ines," "ites," and "phytes" creeping into pharmacy.

DR. J. A. LARRABEE, of Louisville, made the

REPORT ON DISEASES OF CHILDREN.

He referred to the necessity of care for the children for the good of the nation, the harm done in schools, factories, mills, etc. In pædiatrics we must learn the language of disease. This, like other languages, must be learned while young. Other specialties are drifted into,

pædiatrics is not. He considered cholera infantum, syphilis, scrofula, measles, and scarlet fever, whooping-cough, and chicken-pox; advocated hypodermic injection of morphia and atropia in children.

Dr. T. B. Greenberg, of West Point, read a paper on "Cholera; its Etiology and Mode of Propagation."

Dr. L. S. McMurtry, of Danville, made the report on "Gynecology."

Dr. T. D. Finck read a paper on "Strychnine and Mercuric Bichloride in the Treatment of Phthisis."

In the evening an elegant banquet was given by the Crab Orchard Springs Company.

Third Day—Friday, June 6th.

The Committee on a State Board of Examiners reported that the bill prepared by it could not be passed, and recommended one requiring registration of diplomas.

Delegates to American Medical Association were appointed.

Dr. J. B. Harwood, of Shelbyville, reported on "Vital Statistics;" Drs. John G. Cecil, of Louisville, read a paper on "Mastitis;" P. S. Connor, of Cincinnati, on "Fracture of the Neck of the Femur;" F. C. Wilson, Louisville, "Instruments Devised to Facilitate Tracheotomy;" R. M. Ferguson, Louisville, "Treatment of Cross Eyes;" J. G. Carpenter, Stanford, "Exsection of Tibia and Right Fibula;" A. W. Johnson, Danville, "Surgery of the Genito-Urinary Organs."

Adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 22, 1885.

John A. Wyeth, M.D., President, in the Chair.

Report of the Committee on Microscopy.

Dr. L. Waldstein reported that the ulcers of the larynx presented by Dr. Boldt at the last stated meeting were tuberculous in character, and showed the presence of tubercle bacilli. Concerning the clinical question whether or not it was primary tuberculosis, the lungs also being tuberculous, the Committee was unable to answer from the anatomical examination.

Scleroderma.

Dr. H. J. Boldt presented a patient, a girl, twenty-two years of age, who from early childhood noticed a swelling of the left lower extremity, first extending up the thigh, and some years afterward the same kind of swelling appeared in the right lower extremity. At the present time the enlargement of both extremities was permanent, and extended nearly to the body. While walking the limbs increased in size considerably, and gave the patient a good deal of pain, caused great lassitude and general debility, so much so that she was unable to pursue her ordinary occupation, that of a domestic. She had presented herself at a number of clinics in Europe, had been examined by Billroth and others in Vienna, and, as far as he could learn, no positive diagnosis had been made. There was but little pitting on pressure, although there seemed to be an infiltration of the subcellular tissue, and, as Dr. Boldt thought, a probable increase of the fibrous tissue due to recurrences of subacute inflammation. From palpation the diagnosis seemed to be between scleroderma and myxœdema; but, as there was no other sign of myxœdema present, and the feel of the limbs was not well marked according to the descriptions given of that disease, he was inclined to the diagnosis of scleroderma.

Dr. Wesley M. Carpenter thought the case belonged to the class which had already been described under the head of congenital hypertrophy, in which one extremity, either an upper or a lower, first became involved and might remain the only extremity affected, or other extremities were affected and the enlargement became persistent. He referred to a case which came under his own observation in the country; the patient was the daughter of a farmer, and was at the time he saw her about twelve years of age. One of the upper extremities was enlarged, especially the hand and the forearm, and the arm to a less extent. The hand and the forearm were nearly equal in size, and presented the appearance of a limb of an ordinary adult man, rather than the delicate extremity of a girl of that age. As he recollected, the descriptions which had been given of this class of cases, of which he had seen three or four illustrations, the affection had been regarded as a neurosis.

Primary Carcinoma of the Liver.

Dr. L. Waldstein presented two specimens of primary cancer of the liver, with the following histories:

The first case was that of a man, F. K——, fifty-one years of age, who came to the German Hospital on the fourteenth of April last, complaining chiefly of pain in the back, between the shoulders, in the lumbar regions, radiating toward the front. There was jaundice. Physical examination revealed mitral regurgitation with stenosis at the aortic orifice. Besides, there were signs indicating cirrhosis of the liver. The patient gradually grew worse, and died on May 10th.

At the autopsy the liver was found of medium size, appeared granular, and the granulations were very large, but at once it showed differences from the ordinary granular atrophy of the liver in the fact that the granulations were prominent, were arranged in groups, connected by fine bands of the same grayish-white color, and they were encephaloid in consistence. The border of the liver was sharp, and the organ was somewhat enlarged. The hepatic tissue between these granulations was depressed below the level of the section. There was no cancerous primary tumor in any part of the body. The mucous membrane of the stomach was smooth, and was covered with a thick layer of viscid mucus. The kidneys were hyperæmic. The parietal peritoneum contained several small nodules, the largest being about the size of a pea and resembling, on section, the granulations seen on the cut surface of the liver. There was considerable retroperitoneal and bronchial enlargement, and these glands were infiltrated and presented the same general appearance of the granulations mentioned. There was also found a tumor adherent to the posterior surface of the sternum, reaching into the anterior mediastinum.

Microscopical examination of the liver proved the disease to be one of two kinds of primary carcinoma of that organ, the origin of which could be traced distinctly to the small bile-ducts.

Only a month later Dr. Waldstein had an opportunity to make a post-mortem examination in a second case, that of a man, C. J. K——, fifty-three years of age, who was admitted to the German Hospital in a comatose state. No clinical history was obtained. The skin was deeply jaundiced. The man died without a diagnosis. There was œdema of the lungs, ascites, and enlargement of the liver.

At the autopsy the appearance of the blood was tar-like. The liver was very much enlarged, extending below the free border of the ribs 8 ctm. The right lobe was especially increased in size, the omentum was drawn down and attached to the sigmoid flexure. The stomach was dislocated, and lying almost perpendicular, with its fundus pressed against the diaphragm, the pylorus pointing downward and a little to the right. The lungs presented evidence of old catarrhal pneumonia, and there were old pleuritic adhesions. The spleen was enlarged and its capsule shrivelled.

On cutting through the enlarged liver a tumor, double the size of an English walnut, was found situated in the part of the liver tissue directly corresponding to the porta hepatis. The gall-bladder was distended by grayish viscid fluid, without evidence of bile coloring matter. The common bile-duct and the cystic duct were found

patent, and it was demonstrated that the jaundice was caused by pressure of the intrahepatic tumor.

On examining the tumor microscopically it was also found to be primary carcinoma of the liver, but of another form. In the first case, the disease was what is known as diffuse primary carcinoma of the liver, while in the second case the disease was circumscribed primary carcinoma of the liver. But in both instances the cancer originated, not in the liver-cells, not from endothelium, but commenced in the bile-ducts.

Dr. Carpenter remarked that primary carcinoma of the liver was so exceedingly rare that a special interest was attached to Dr. Waldstein's two specimens obtained within such a short period of time.

The President said that he had seen one specimen of primary carcinoma of the liver.

Dr. G. A. Dixon presented a specimen of

ANEURISM OF THE ARCH OF THE AORTA,

with the following history:

C. T——, male, native of Finland, longshoreman, was admitted to Charity Hospital March 2, 1885, and died March 29, 1885. Family history negative. The patient stated that he had always been perfectly well up to the winter of 1884, when while walking in the street he suddenly became unconscious, was taken to Bellevue Hospital, where he very soon regained consciousness and found that his left arm and leg were paralyzed. At the end of five days this paralysis began to diminish, and on the ninth day he was able to walk from the hospital, the paralysis having entirely disappeared. There has never been any return of this trouble.

Present attack.—Patient noticed in July, 1884, that he had a slight dry cough and that he began to lose strength. This continued up to January, 1885, when he suddenly became very hoarse, which has continued to grow worse. Throat never has been and is not sore.

Two weeks before admission he noticed that his sputa was streaked with blood. On the day before admission to hospital patient had a very severe hemorrhage, "filling a large washbasin with bright red blood."

On admission to hospital patient was a stout, well-nourished man. Had slight dyspnœa. Voice was reduced to a whisper. The laryngoscope showed paralysis of the left vocal cord.

Physical examination.—Inspection showed veins over left side of chest very prominent. There was a heaving impulse over quite a large area below the left clavicle. Apex-beat of heart in normal position. On percussion the area of cardiac dulness was slightly increased. On the left side, from the clavicle to upper margin of third intercostal space, there was flatness, and to the right of sternum, from the lower border of the clavicle above to the third intercostal space below, extending an inch and a quarter to the right, there was dulness.

Auscultation.—At the apex there are no murmurs. At the base there was heard a loud double murmur, and to the right of sternum, at about the second costal cartilage, there was heard a very loud double bruit, which was heard with maximum intensity on introducing stethoscope into patient's mouth. Liver and spleen were normal in size. Urine contained a trace of albumen. Patient denied any venereal disease; had never been a drinker; and no history of fall or injury could be obtained. Was ordered iodide of potassium, ten grains, three times a day, to be increased, recumbent posture, and a minimum of fluids. Patient remained in about the same condition. On the morning of March 29th he handed his sputa-cup to an orderly, uttered a groan, and died inside of five minutes.

Autopsy.—Brain could not be examined. Lungs were everywhere closely adherent to pleuræ. They were congested. At the base of the left lung a space of about two inches in circumference was filled with clotted blood, and a very minute opening was found into aorta. Heart was enlarged and hypertrophied. Mitral valves slightly thickened. Aortic valves very much thickened. The entire arch of aorta was enormously increased in size and presented all stages of atheroma. Liver and spleen normal. Kidneys showed slight interstitial nephritis.

The President said that when he was connected with Bellevue Hospital he made an autopsy on a man who died under circumstances not unlike those related by Dr. Dixon, and there was found an aneurism of the descending aorta into which a small opening had been made by pressure against the vertebral column. The patient died gradually. The left pleural cavity was found filled with blood which had escaped through the small opening.

Dr. Thayer referred to a case which occurred in the New York Hospital last summer, which resembled the one reported by Dr. Dixon, first, in the obscurity of the diagnosis. The patient was a painter, who gave a syphilitic history. There was almost no tumor of the chest, but finally a slight bulging of the intercostal spaces developed, which rapidly increased until it made a large tumor, 15 ctm. in diameter, of a general spheroidal shape, over which marked pulsation could be felt, with œdema of the tissues, ecchymotic spots, and double friction-sound. The man died suddenly. At the autopsy there was found a small aneurism of a sinus of Valsalva, and upon this a large aneurismal sac had been formed which had eroded the third, fourth, and fifth ribs with their intercostal cartilages, and would apparently have burst within a few hours, as the sac was exceedingly thin. There had not, however, been any rupture of the aneurism. The original aneurism was intrapericardial; the secondary aneurism was entirely outside of the pericardial sac.

Another point of interest in the case was the result of electrolysis, which was tried two or three times. Around the points where the needles had been inserted there was a distinct increase in the thickness of the clot and an evident decrease in the size of the cavity of the tumor, but there were also marked ulcerations which perhaps would have been fatal had the patient survived a little longer.

PURULENT PERICARDITIS—EMPYEMA.

Dr. Thayer also presented the heart and pericardium of a man about forty years of age, who entered New York Hospital with obscure pulmonary signs early in December last. He was thought to have pneumonia, and many of the symptoms characteristic of pneumonia were present, such as bloody sputa, high temperature, etc., but notwithstanding this the patient appeared to be doing very well. Within a few days, however, the case took an unfavorable turn, the pulse grew weak, emaciation occurred, there was afternoon elevation of the temperature, respirations from twenty-five to thirty in the minute, and the pulse above 100 constantly. The change from bad to worse was rapid, and the patient died without special symptoms. Repeated physical examinations of the chest had been made, and the area of cardiac dulness had been carefully noted many times during the patient's illness up to twelve days before his death. He complained of a feeling of compression of the chest which had led to the suspicion of pericarditis, but nothing, however, was found to indicate its existence.

At the autopsy the right pleural cavity was found half filled with thick creamy pus, and the lung showed evidence of recent pneumonic process which had nearly disappeared. The pericardium was distended, and contained a large quantity of pus. All over the visceral surface of the pericardium was a thick layer of pyogenic membrane, continuous with a similar layer over the parietal pericardium. The chief interest in the case centred in the fact that, although careful examination was repeatedly made, pericarditis was not diagnosticated.

Dr. L. Emmet Holt presented

THE PETROUS PORTION OF A TEMPORAL BONE,

accompanied by the following history:

T. M——, aged five years, was seen Friday, April 17th, at the Northwestern Dispensary. He was carried in the

arms of his grandmother, who gave the following history: He had had a chronic otorrhea of the left side since infancy; measles two years ago, never scarlatina; discharge had been tolerably free until two days ago, when it was reported to have ceased. On Wednesday and Thursday he was able to go down in the yard to play, though complaining of severe pain in his left ear. All day Friday he had been quite drowsy, vomiting frequently, bowels being constipated until an injection was given, then moving freely. His rectal temperature was 101° F., his pulse 120. The head was slightly drawn backward. There was slight swelling below the left ear, no redness, no fluctuation. He was pale and disposed to be quiet, but easily roused; pupils normal, tongue coated. He appeared to be quite sick. About six o'clock he was reported to have had a sort of chill; passed a quiet night, taking his milk, but vomiting it in curds. Early Saturday morning asked to be taken up to pass water; said he felt weak and wanted to be put back to bed; called for water to drink, gasped, and died. No convulsions at any time and no paralysis; no loss of consciousness.

Autopsy.—Fifty hours after death. Head: on removing the skull vessels of pia showed marked engorgement; brain showed punctate congestion, but was othewise normal. No fluid in lateral ventricles, nothing found on careful examination of medulla or fourth ventricle; no evidence of inflammation over pia or inner surface of dura. On opening the petrous portion of the temporal bone the middle ear was found filled with very fetid pus, about a drachm in amount, the bony walls carious and so disintegrated as not to be recognizable. This seemed to communicate with the external swelling, probably following the seventh nerve. There was pachymeningitis externa over an area the size of half a dollar, covering the diseased part of bone, and a small accumulation of pus here. Unfortunately the sinuses were not carefully examined. Chest: lungs were somewhat congested and markedly œdematous, but showed neither abscesses nor tubercle; no pleurisy. Pericardium contained about an ounce of clear serum, no signs of inflammation being present. The heart was relaxed, its tissue a little paler than normal, the right side contained a soft clot; velus, normal. Nothing of pathological interest was found in the *abdominal organs*, except in the spleen, which was very large, measuring about five by three inches. It was firmer than normal, yielded a grumous material on section, was free from abscesses. None were found elsewhere. It was not the spleen of septicæmia.

In reviewing the case, the explanation of the symptoms and the cause of death did not seem altogether clear. While the immediate cause seemed to be, without much doubt, heart-failure and pulmonary œdema, the remote cause was not so evident. Was it septicæmia, or was it simply pachymeningitis? Dr. Holt was inclined to accept the latter hypothesis as the more probable one.

Dr. W. M. Carpenter thought that death in Dr. Holt's case could be satisfactorily explained by the sudden development of pulmonary œdema. While the exact explanation of the sudden development of pulmonary œdema had perhaps not been satisfactorily given, the clinical fact remained that it occurred not infrequently, and especially in that class of cases in which the patient had been brought into a low condition from some preceding disease. Not infrequently, patients who had suffered, for example, from pneumonia, and in whom convalescence seemed to be well established, on rising to empty the bladder, as in Dr. Holt's case, were soon taken with pulmonary œdema and died within a very short time.

Dr. Garrish referred to the fact that death from meningitis, secondary to middle-ear disease, was not infrequent.

Dr. Boldt recalled two cases, one of which Dr. Janeway saw, and in both of which it was impossible to make a diagnosis. In both instances the patients died suddenly, and with pulmonary œdema. The autopsies were made by Dr. Janeway, and pachymeningitis was found only after very diligent search. That pulmonary œdema might develop suddenly with pachymeningitis and kill the patient was not so infrequent as might perhaps be supposed, for here were two cases in which the two conditions existed as verified at autopsy. What the exac connection was between the two it was difficult to say.

The Society then went into executive session.

Correspondence.

DR. FERRÁN'S EXPERIMENTS.

To the Editor of The Medical Record.

Sir: It is but natural that the public should take a deep interest in the result of the experiments of Dr. Ferrán, in vaccinating with attenuated cholera virus. Any prophylactic against a disease so dreaded and feared as cholera will be hailed as a boon to mankind.

The progress of Dr. F.'s experiments is noted most flatteringly by the public press, and even medical journals echo the favorable reports in a half-hopeful manner. I fear, however, that these longing expectations are only born of hope. It is true that we vaccinate as a preventive of variola, but we have this fundamental principle to start with—that one attack of variola gives, as a rule, exemption against any subsequent attack. If one attack of cholera conferred exemption against a subsequent attack, we could look to protective vaccination with much more confidence. From what I have seen of the disease, and from those who have observed all the epidemics of the disease that have occurred in this country, I find no warrant for belief that one attack of cholera may not be followed by another in the same person. Most authors make no reference to this point. Goodeve, in "Reynolds' System of Medicine," vol. i., p. 392, states that there are numerous cases on record of persons who have had cholera more than once.

Roberts, part i., p. 219, says: "One attack does not afford protection against another." So far as I am aware, this is the uniform testimony of all who have expressed their views on this feature of cholera.

Now, if an unmitigated attack of Asiatic cholera in its worst form confers no exemption from a subsequent attack, I see no reason to hope that vaccination with attenuated virus will confer any possible degree of exemption or protection. Benjamin Edson, M.D.

DUODENO-CHOLECYSTOSTOMY.

To the Editor of The Medical Record.

Sir: I have intentionally postponed my reply to your note of February 14th, offering me a hearing on the subject of my operation, until some notice of it might appear from abroad. Now that we have a domestic and foreign estimate of this proposed "abnormal cysto-intestinal communication," claiming that whatever merit attaches to it belongs to the so-styled "originals of this proceeding," and not to my improvement upon the process, it seems proper to define exactly my position. The comments upon my mode of uniting the gall-bladder and the duodenum, for the relief of obstruction in the gall-duct, have manifested a want of due appreciation of the main object, in restoring the bile to the alimentary canal near to its normal entrance. If it be conceded that the bile subserves an important end in chymification, and in the preparation of the chyle for the nutrition of the body, with promotion of the peristaltic intestinal action, and correction of fecal decomposition, there can exist no doubt in regard to the importance of introducing it into the duodenum by a fistulous opening from the gall-bladder. It only remains then to determine upon the practicability of effecting this end with safety, and so as not to incur subsequent trouble in the proceeding. This must rest upon a rational inference from my experiments

on dogs, illustrating the union by adhesive inflammation of the outer surfaces of the intestine and gall-bladder, and the maintenance of an opening between them, by ligation of their walls together. In my last experiment, eight days after the primary operation, for simple ligation of the gall-bladder to the duodenum with a silk thread, "the exploration revealed union of the gall-bladder and duodenum, with adhesions of the latter to the lower surface of the liver, over the line traversed by the *cystic gall-duct*, so that it was not practicable to ligate it, as was intended. Neither could the *ductus choledochus* be reached; and yet no doubt existed of the exit by an opening between the gall-bladder and duodenum, as the small size of the gall-bladder indicates that it is kept drained." The *Birmingham Medical Review* "cannot help wondering," after reading the above passage afresh, on the last page of that "extraordinary little brochure," that I had discovered the difference of the cystic gall-duct and the ductus choledochus at least in the dog.

The animal above referred to continued well and quite sprightly for five months; when, on the eve of another experiment, it succumbed from an excessive inhalation of sulphuric ether. But the examination revealed that the most thorough agglutination of the walls effected a compact septum between the gall-bladder and duodenum; while the orifice formed by the ligature had been obliterated, from the fact, no doubt, that the natural channel of the bile was unembarrassed, as was proven by passing the probe through the ducts.[1]

It is an important feature in the history of this experiment, that no undue inflammatory action was set up in the peritoneal cavity, nor did the bile-ducts become involved in the inflammatory action propagated from the ligature to the neighboring serous investments of the gall-bladder and duodenum. The fatal results in the other experiments were owing to the lack of proper precautions in the subsequent treatment; and due likewise, in some of the animals, to the circular row of stitches around the ligature, which is found to be quite unnecessary as well as injurious.

The idea that there may be regurgitation of the chyme into the gall-bladder through a fistulous opening is set aside by the *vis-a-tergo* urging the bile out into the duodenum.

Very respectfully yours,
I. McF. Gaston, M.D.

"A MEDICAL VIEW OF ARMY MORALS."

To the Editor of The Medical Record.

Sir: Under the above caption, The Record of June 13th makes an extract from *Col. Med. Journ.* This article is a gross injustice to the "soldiers of America."

While freely admitting that army life tends to the lowering of the standard of morals, and the removal of many restraining influences, yet the opportunities for the gratification of immoral instincts were less during the war of the rebellion among soldiers in the field than among private citizens either then or now. The abovementioned extract is pleasant reading for the young medical student "*whose father had been in the army.*" American soldiers, both Blue and Gray, deserved better treatment at the hands of physicians. Aside from that, it is untrue. Lack of proper food and prison life, diarrhœa, scurvy, and other chronic diseases were sufficient causes for scrofulous offspring.

In three hundred and eighty careful and prolonged examinations of soldiers, made during the last year, and which examinations are carefully recorded, in only one was positive evidence of syphilis found, and in five only was there presumptive evidence.

These examinations were many of them made for the very purpose of determining whether or not a "specific" disease existed. Take the young men to-day between twenty and thirty-five years of age, and you will find a much larger proportion with evidences of *acquired* syphilis. Take any calling or profession in America and the proportion will be equal, not excepting the clergy, college professors, and editors.

If the statement is true medical examiners for life insurance have been very neglectful in the past, and should rigidly exclude soldiers from the list in the future.

We think the Editor of the *Col. Med. Journ.* possibly mistaken, and if he is correct, a careful examination of soldiers now living will show that Professor Gross was mistaken.

Geo. T. McCoy, M.D.

Columbus, Ind., June 20, 1885.

New Instruments.

THE POCKET POLARISCOPE.

By C. A. Bucklin, M.D.

New York.

This is the first instrument manufactured in America for the purpose of testing pebble lenses, the tourmaline tongs being almost exclusively manufactured in France or England.

It consists of a small nickel cylinder, with a slot at right angles to its axis, into which any lens to be tested is placed. Each end of this cylinder is closed by a perforated head, the opening in each head is closed by a plate of tourmaline, the axes of which are at right angles to each other. Tourmaline having the peculiar optical property of allowing light to pass through it in only one plane, the light which comes through the first plate is entirely absorbed when it falls upon the second piece of tourmaline, consequently, it is impossible to see any light through the opening. When a pebble lens is placed in the slot the light comes through the instrument beautifully; but when a glass lens is placed in the slot it is impossible to see any light. The quartz, of which the pebble lens is made, possesses a circular polarization, thus the light which passes through the first plate is so twisted by the pebble that it falls on the proper axis to pass through the second plate of tourmaline.

The question is frequently asked physicians as well as oculists, "Doctor, do you know whether these glasses are pebble or not?" The moment one of them is placed in the slot of this instrument, and you attempt to look at the light, the question is decided beyond criticism. If they are pebble, you see light; if they are glass, you see nothing.

It is an amusing fact that the simplicity and perfection of this little instrument has caused the further importation of all foreign appliances for similar purposes to be abandoned.

A Case of Poisoning by Cannabis Indica—Recovery.—Dr. Thomas W. Lauterborn, of Newark, N. J., writes : "Hemp of India has been largely employed in my practice for cephalalgia at the menopause, and with very uniformly positive benefits. Hence, when I was called in to see a case of this description, several months ago, I ordered the following :

℞. Tinct. cannabis indicæ..... ♏ lxxx.
Pulv. acaciæ..... ʒ ijss.
Syr. aurantii cort..... ʒ iv.
Aq. camphoræ.....q. s. ad ʒ iv.

M. Sig.—Tablespoonful every three hours until headache relieved.

"This prescription was used with decided benefit, the headache being most effectually kept under control by only a few doses as occasion required. Several weeks ago, having been out of the medicine for some time, the pain began to assert itself again, and the bottle was sent to the druggist for replenishing. The pharmacist, whom I know to be not only well educated, but a man of more than ordinary care and neatness, in some unaccountable way took the *fluid extract* of hemp of India, instead of the *tincture*, and filled the prescription. Consequently every tablespoonful of the mixture represented ten (10) minims of the fluid extract, equal to ten (10) grains of the solid extract. About an hour after taking the first dose she began to complain of a boiling sensation at the top of the head, and whenever she raised her eyes toward the ceiling a sensation as if the top of her head was being pulled off by someone standing behind her, and it was all she could do to keep from falling over backward. She lay down on a lounge in consequence, but the boiling, forcible beating, and lifting up of the vertex increasing, she resorted to another tablespoonful of the medicine. Her son, who was engaged in reading to her, was astonished soon afterward by being implored to hold her down, and not let her be pulled up into the air, and to speak louder and more distinctly. Her complainings growing more serious, he laid his book aside, and thinking to cheer her by conversation, he mentioned several little incidents which had occurred in the house that morning. To each and every one his mother exclaimed in a dreamy tone, 'Oh, tell me something new, that took place one hundred years ago.' Suddenly she struck her hand violently against the wall, sprang up with a wild and terrified cry, clutching her vertex with one hand and the precordia with the other, gasping for breath, and loosening her dress about the heart. 'I am dying, oh, I am dying,' she piteously gasped ; then her face lightened up with a rapturous smile, she sprang to the unfortunate medicine bottle, exclaiming, 'Oh, what a perfectly lovely bottle,' and removing the cork, placed the bottle to her lips and took two swallows. 'Oh, how terribly hungry I am,' she exclaimed, as she set down the bottle, and coming to the table upon which stood the dessert for dinner, she began indiscriminately and rapidly to eat everything. Two medium-sized oranges were disposed of in a moment, rind and seeds ; a large plate of cake followed ; then a large dish of peanuts claimed her attention, putting three and four in her mouth at one time, munching as rapidly as possible, and swallowing shells and all. I was immediately sent for, as was her husband. When I arrived I found her hopping around the room in a perfect ecstasy of wild delight. She would suddenly elevate both arms above her head, beat the air like a pair of wings, give a spring upward and forward on one leg, kicking the other in the air, her face beaming with delight, eyes glowing and sparkling. Then, as if conscious where she was and who was about her, she would stop an instant, snap both thumbs, give us a contemptuous look, and resume her previous antics. Once she ran to her husband, fell upon his neck and, with a torrent of tears and hysterical sobs, besought him not to send her to an insane asylum. I spoke to her several times, asking her how she felt, and each time she acted as if her mind was confused, putting her hand to her head and saying, 'Oh let me think,' corrugating her brows and apparently struggling hard to recall something, but failing every time. While she was cogitating I noticed that her eyes were suffused, face flushed, her pupils evenly contracted and unresponsive to light. The pulse was beating 100 per minute, generally each wave of short duration, its volume small, very compressible, irregular both in length and force, besides being intermittent. The thermometer could not be retained in her mouth longer than one and a half minute, but in four or five trials always remained at 98⅘°. Sensation in hands and skin of forearms was markedly impaired. A prick of a needle that drew blood was not felt. Hands were cold to the touch. I had at first not the slightest idea what ailed my patient, but her husband called my attention to the fact that the second bottle of medicine was entirely different from the first, both as regards color and taste. Filled with the most serious apprehensions now, I directed her husband to take her out in the yard and walk her briskly up and down, while I took the bottle and hastened to the pharmacist. He was positive that he had made no error, and to prove it proposed immediately to compound the prescription and compare the two bottles ; this was done, and on placing them side by side a startling difference was at once apparent. The poisonous bottle was of a dark-green color, whereas the one just compounded was very pale-green. The error then was discovered. What to do was now the question. Emetics first, to remove not only whatever poison might still be remaining in the stomach, but the mass of indigestible material which she had eaten, and free stimulation afterward ; for if ever there was a pulse in which all the indications for stimulants were complete, then it was this one. So, armed with a solution of sulphate of zinc (ʒ ss. to ʒ iij. of water), and fortified with a big bottle of brandy, I hastened back to the house. I had been gone three quarters of an hour, during which time the patient had been walked up and down in the yard in a rain-storm. Most of the time she talked incessantly and incoherently, laughed idiotically, cried hysterically, screamed with terror, hopped with delight. Some of the neighbors were looking on ; she recognized them, called them by name, and attempted to speak, but her utterance was thick, and ideas all confused, so that her sentences were not connected and bore no relation to each other. She was brought into the house upon my return. The stage of excitement had passed, and exhaustion or depression began to appear. I administered the emetic, and gave a half-pint of warm water with a heaped-up teaspoonful of strong mustard in it to drink ; within five minutes she began to complain of intense burning at the pit of the stomach and copious vomiting ensued. Two teaspoonfuls of brandy were administered every half hour. She complained of a severe and continual pricking and tingling over the entire body, most marked in the hands and feet. Her tongue, mouth, and throat were

dry. She could not collect her thoughts sufficiently for any conversation, and seemed wild and distressed. She started up from the chair every few minutes, walked around the room beating and briskly rubbing her hands and stamping her feet. Her hands were cold, numb, slightly blue, and full of 'pins and needles.' Her feet were in the same condition. She was inclined to go to sleep each time upon returning to her chair. She mentioned that she could not feel her feet touching the floor distinctly as she walked. Pulse, 100, feeble, compressible, irregular, intermittent. Temperature, 98⅗°. Cutaneous sensibility on back of hands and forearms nearly normal. Late at night she was sufficiently strengthened and collected to give the following description of her sensations: 'About an hour after taking the medicine I began to experience a creeping sensation in the top of my head, as if a piece of thread was being drawn over the surface of the brain. This increasing in intensity, I felt as if the surface of the brain was working up and down against my skull. A faint tingling then became manifest in my fingers. Feeling that my head was growing worse, I took another dose of the medicine. My little boy was reading to me, and presently his voice began to sound afar off; I felt that I was rapidly getting farther and farther away from him, drifting I knew not whither, and that years had elapsed since last he had spoken to me. Presently he began to talk about some little things which had occurred that morning in the house, and I wondered how old they were, seemingly having occurred one hundred years ago. My brain now began to feel as if it were boiling, and frequently a sensation occurred as if the top of my head was lifted off, and the contents had boiled over. With each boiling over I felt as if a thousand needles were pricking me all over, more especially in the hands and feet, so that I was mortally afraid to move either for fear of running them further into me. Then my mouth and throat became parched, my tongue seemed to cleave to the roof of my mouth, the stinging in hands and feet became unendurable. Whenever I opened my eyes the whole top of my head fell off over backward, inclining me to fall over also, and a deathly sinking, fainting sensation ran through me. Then I lost all control over myself, a ravenous appetite took possession of me, and something within me whispered to take more of the medicine. I was fascinated immediately by its sweetish taste, and was drawn toward it by a force which I felt powerless to resist. I seemed to be conscious what I was doing, recognized everything about me, but could not control myself. I seemed to be myself and somebody else. After tasting the medicine and then taking two good swallows, I began to eat everything I could lay hands on. Then I was lifted up into the air, and thought I was in heaven. The whole earth was beneath me, I spurned it with my foot as dirt, and floated about in space, cognizant of all that was going on about me, but utterly indifferent and blissfully content. A feeling of great ecstasy ran over me at times, and I had to hop, dance, and cry out, for the joy was too great of being away from the earth. I seemed to possess two spirits, and to dwell in two different estates; dreamily conscious of those around me, yet dwelling amid visions of the sublime. I felt like speaking to those around, to come up to where I was and view with me the grand and gorgeous scenes, but the hopelessness of speaking through the immense space which separated us soon impressed itself upon me and I became silent. The most glowing landscapes were continually passing before my view like a panorama, each more gorgeous, grand, and sublime than the preceding. Gradually, however, they began to fade, I was approaching the earth, and once more felt myself among you.' The action of cannabis indica on the various structures and organs of the body may be summarily stated. 1. On brain and nervous system: In small doses it gently exhilarates the brain. In sufficient quantity the imaginative and emotional faculties are stimulated, then deranged—finally disordered. The conceit of the individual is markedly developed. The ideas pass through the mind in an overwhelming, continuous, rapid succession, but without any connection, and lead to no result beneficial to individual or community. The higher intellectual faculties, *i.e.*, memory, judgment, volition, are disordered. The special senses of sight and sound are disordered. The sensory nerves are rendered incapable of receiving or transmitting impressions. The brain is actively congested. No action on the reflex function of the spinal cord. The sympathetic system of nerves is stimulated. 2. On vascular system: The heart beats more rapidly, but it is due to weakness, *not* to increased force. The pulse becomes frequent, quick, small, compressible, irregular, and intermittent. 3. On respiration: None. 4. On temperature: None. 5. On digestive organs: No nausea excited; on the contrary, a great desire for food. No constipation follows its use. 6. On secretions: The salivary juices were diminished, producing dryness of mouth, tongue, and throat. No apparent effect upon gastric, biliary, or intestinal secretions. 7. On excretions: Urine increased in quantity, and had an odor of the drug. No diaphoretic action. Fæces natural in amount, color, and consistency."

The Cause of the Excessive Mydriatic Action of some Specimens of Cocaine.—At a meeting of the Paris Academy of Medicine Dr. Panas gave an account of some investigations undertaken at his suggestion to determine the cause of the excessive mydriatic action sometimes seen in cocaine. It was found that some manufacturers submitted the leaves to a second treatment, in a desire to obtain every particle of the alkaloid, and that during this process a new substance was produced. This second alkaloid was hygrine, a substance possessing marked mydriatic properties. In experimenting with two samples of cocaine, one of undoubted purity and the other presumably containing hygrine, Dr. Panas found a great difference in their mydriatic action. The first sample caused only a moderate dilatation of the pupil, while the second dilated the pupil widely, and its effects continued for forty-eight hours. The mydriasis of impure cocaine differs from that of atropine in that it yields quickly and entirely to the action of eserine, while the alkaloid of belladonna is only momentarily antagonized by this substance.

The British Pharmacopœia.—The new British Pharmacopœia will shortly be issued, and will contain, it is said, over one thousand preparations. A number of new drugs will be introduced for the first time, among which are apomorphia, pilocarpine, kairine, menthol, iodoform, the oleates, vaseline, thymol, salicylic acid, and the salicylates. Not very many of the present officinal drugs will be rejected, and it is expected that the Pharmacopœia will still contain a good deal of what some therapeutists call "rubbish." There is some talk of introducing the metric system.

The Overcrowded Profession.—Those who are disposed to find fault with the overcrowded condition of the medical profession in our country, may find some slight solace in the fact that matters are not much better in some other parts of the world. In Vienna this would seem to be especially noticeable. According to the *Progrès Medical*, physicians are more numerous in the Austrian capital than in any other city in Europe; there are ten times as many in proportion to the population as in London. This implies a dismal prospect for the younger men, who must be content with very modest fees. One practitioner (whose name is not mentioned) is credited with forty thousand dollars a year, but the rest "*ont tout lieu de désespérer*." There is a great deal of complaint against the vast system of medical charities, which are extended indiscriminately and are taken advantage of by patients who are amply able to pay a physician.

The Medical Record

THE ACRO-NEUROSES.[1]

Functional Nervous Affections of the Extremities.

[By C. L. DANA, M.D.,

Professor of Nervous and Mental Diseases, New York Post-Graduate Medical School; Professor of Physiology, Woman's Medical College of New York.

Some elaborate works have been written upon the subjects of the anatomy, physiology, and pathology of the hands and feet. So far as the last is concerned, however, systematic writers have discussed chiefly the surgery and the deformities of these members. It has occurred to me that it might be instructive to collect the numerous and wide-scattered contributions to the medical pathology of these parts. I have felt a particular interest in doing so from having met in practice types of many of these affections, and from having observed some forms which are apparently unique.

The hands and feet being highly specialized organs, are naturally subject to frequent and considerable changes in their blood-supply and nervous conditions. Besides their natural high sensibility and delicate mechanism they have certain anatomical relations, being remotely removed from the heart and nerve-centres, which put them at a disadvantage. Changes in circulation, secretion, temperature, sensation, as well as in motor power are therefore not rarely observed. All these changes, when of nervous origin and not due to any known organic disease, may be spoken of as neuroses of the extremities, or as acro-neuroses, a term which is convenient and quite as justifiable, it seems to me, as that of neuroses of the stomach, bladder, or any other complex organ.

Many peculiar neuroses of the extremities have been noted by physicians. Some of them may appear trivial, but in all cases they at times cause distress, and often such agony and misery as to interfere with the last two at least of the Jeffersonian functions, "liberty and the pursuit of happiness."

The different affections of the extremities which we may provisionally call neuroses can be with approximate accuracy classified as follows:

I. Vaso-motor and Trophic Disturbances.—Erythromelalgia; Digiti mortui, or dead fingers; local asphyxia; local syncope; symmetrical gangrene. All these constitute simply different types of Raynaud's Disease.

II. Sensory Disturbances.—*Paræsthesiæ:* Burning hands and feet (ignipedites); ordinary forms of paræsthesia.

Hyperæsthesia.

Neuralgias: Acrodynia; Ignipedites—a special constitutional disease; Reflex neuralgias; Morton's "luxation" neuralgia.

Tarsalgia; Pododynia, Talalgia, Policeman's disease; Spastic neuralgia of Mitchell—different names for same trouble.

III. Secretory Disturbances.—Palmar and plantar hyperidrosis.

IV. Motor Disturbances.—Hysterical, choreic, and epileptic movements.

I shall have very little to say, except about the vaso-motor and sensory troubles, since it is with perplexing types of these that I have personally had to deal, and it is concerning these that much confusion has existed.

I. *The vaso-motor and trophic Acro-neuroses, Digiti mortui, Erythromelalgia, Raynaud's Disease.*

Case I.—A young man, about twenty-four years of age, whom I had been treating for spinal irritation of a depressive type, complained that on slight exposure to cold the ring-finger of one hand became white, waxy, and bloodless. It felt cold, and as though it were separate from the hand. After a time, the circulation becoming restored, there was a burning, tingling feeling experienced. Later the middle-finger became affected in the same way, and the trouble was progressively invading the whole hand when arrested by tonic treatment.

Case II.—I was consulted by Dr. Richards, of Trenton, N. Y., about a young woman of a hysterical temperament. Her history was that after exposure of the hands to cold one of the fingers of the hand became for a time cold, waxy, and as if dead. Gradually the trouble extended until all the fingers of both hands became subject to these paroxysms of local syncope. There was no burning or pain, and no blueness or mottling of the skin. After a time, under the use of strychnine, quinine, iron, and phosphoric acid, she improved, but still suffers in a measure from the attacks.

Case III.—A young woman, single, aged twenty-two, suffered three years ago from fugitive urticaria with intense pruritus, cured by jaborandi. She now complains of frequent attacks of headache. She also suffers from cold hands and feet. The fingers at times get white and waxy, feel dead, then they get blotchy and purple, and the hand swells. No sensory troubles in the intervals of the attacks.

These are cases representing different degrees of a morbid condition, known as *digiti mortui* or dead fingers.

It is not very uncommon in its mildest form, occurring chiefly in women, and in persons of a neurotic temperament. The severe type, in which the fingers and hands get blotchy, purplish, with trophic changes, is much rarer. It is then generally accompanied with burning pain, is more chronic in course and more intractable to treatment.

It then also is recognized under the name suggested by Dr. S. Weir Mitchell, of erythromelalgia, *i.e.*, the red neuralgia,[1] or under that of local asphyxia and local syncope, a name given by Dr. M. Renaud.

A bibliographical history of these morbid conditions is given later on. It appears to me from a careful reading of all of Mitchell's cases, and of many of Reynaud's, that these two observers have independently described closely allied, if not identical diseases.

I venture, however, to give a brief description of erythromelalgia, as observed by Mitchell, and also of local asphyxia, local syncope, and symmetrical gangrene, the periphrastical name given by M. Raynaud to what is better called simply "Raynaud's disease."

Erythromelagia is a painful affection of the extremities, generally of the feet, accompanied by a flushing and

[1] The word acro-neurosis is derived from the Greek word ἄκρον, extremity, and neurosis. The word ἄκρεα was frequently used by Greek physicians to denote extremities. Acrodynia from ἄκρος and ὀδύνη, pain, is a word first suggested by Chardon, and has become a part of medical nomenclature. So that I cannot be accused of coining a new word, but rather of employing a root already in accepted use.;

[1] From ἐρυθρος, red; μελος, a member; ἀλγος, pain. The condition was first described by Dr. S. Weir Mitchell, in the American Journal of Medical Sciences, July, 1878. Dr. Mitchell refers to somewhat similar cases reported by M. Grener, Le Bordeaux Médical, September, 1873; by Vulpian, Le Appareil Vaso-motor, t. ii., p. 623; and by Graves, Clinical Lectures, 1864, p. 826. Since his article other similar cases have been reported or referred to by Ross, T. B. Curtis, Charles K. Mills, and Woodnut. (See Bibliogr., History of Reynaud's Disease.)

mottling of the parts upon slight exertion. It may attack the toes symmetrically and progressively. The patient suffers from an intense *burning* pain in the toes, ball, dorsum, or heel of the foot, extending even up the leg. This pain is relieved by rest and the horizontal position. Trophic changes may finally set in, and evidences of organic spinal disease have been observed in some cases. The hands are sometimes involved, or are even the only seat of the disease. It occurs oftenest in males at the ages of twenty to forty, and comes on after prostrating fevers, severe exercise, or exposure. Dr. Mitchell found the disease very chronic and progressive, and not amenable to treatment.

Erythromelalgia is believed by Ross to be simply a form of sciatica affecting the plantar branches of the posterior tibial nerve. In a case under Dr. Ross' care, as in some of Mitchell's cases, the area of redness and burning corresponded with the distribution of these nerves.

The progressive and symmetrical character of the disease, the remarkable vaso-motor disturbances, the fact that the hands sometimes become involved, show that it is more than a form of sciatic neuralgia.[1]

Raynaud's disease.—Digiti mortui, local asphyxia, and symmetrical gangrene, or Raynaud's disease, belongs, as we have said, to the same category with erythromelalgia. The symptoms of a mild case have been given; those of a well-marked case are very striking. The patient suffers from paroxysms, in which the fingers, toes, and sometimes the ears, tip of the nose, and even tongue become white, bloodless, and feel cold and dead; or, in other cases there is a venous stasis, and the extremities become blue and mottled. As the attack subsides there is pain of a burning character, and often of a frightful intensity. Here we have, therefore, an erythromelalgia. In many cases the disease does not go any further than this, but after a few months gradually disappears. In other cases a symmetrical dry gangrene follows, or this may even come on directly. The gangrene is slight in amount, and rarely causes more than a superficial destruction of tissue. Sometimes the disease runs a very chronic course, lasting for years.

It occurs generally (in France at least) in women between the ages of eighteen and thirty. It seems to be caused in some cases by malarial poison. In two cases (Raynaud's and Barlow's) the patients had diabetes. It has been observed by Armaingand (*Rev. Sc. Med.*, x., 548) to occur as part of the phenomena of a hysterical attack. It occurs in functional paralyses of the arms. Finally, local asphyxia is one of the most marked features in one of the types of scleroderma. More than half a dozen observers, including Grasset, Hallopeau, and Bernhardt, have published cases showing this relation between local asphyxia and scleroderma, and maintaining that there is an essential unity in the pathology of the two affections.

We have, therefore, on one extreme scleroderma, a serious chronic trophoneurosis, and on the other the mild types of "digiti mortui," of slight significance.

In all these there is a tetanus of the peripheral vessels, due, no doubt, generally to an excess in reflex sensibility of the vascular apparatus, since the affection is symmetrical and paroxysmal. In some of the types sensory and trophic, as well as vascular, nerves may be directly involved.

What the cause of Reynaud's disease is we do not know. So far no organic lesion has been discovered. It does not seem to be of an infective character. It occurs in persons of an extremely mobile nervous system. Malaria or diabetes, exhausting diseases, over-work, and mental strain are concerned with the etiology in most cases. The disease can be easily distinguished from gangrenous ergotism, and from gangrene due to impaired nutrition, or to toxic agents of any kind, by its spontaneous development and its symmetrical and paroxysmal character.

Raynaud has stated that galvanic currents to the back and extremities are very efficient in treatment. These should be supplemented by rest, local stimulation, tonics, good food, etc.[1]

(To be continued.)

[1] A condition resembling erythromelalgia has been observed in arsenic poisoning by Dr. E. C. Seguio, Jour. Nerv. and Ment. Dis., October, 1882.

ON THE CLASSIFICATION OF DEAF PUPILS WITH A VIEW TO IMPROVE THE FACILITIES FOR THEIR EDUCATION, BASED ON THE CAUSES OF THEIR DISABILITY.[2]

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

THE existence of deafness is not discovered even by discerning parents during the first few weeks of infancy, and what is frequently a mere suspicion in this regard at the sixth month may not become a painful reality before the child is expected to talk, and then the slowness of intellectual development may not be properly attributed to defective hearing. Partial, but disqualifying, deafness is thus liable to be overlooked until school education is attempted.

The detection of the very existence of hearing defects, it may be premised, is attended with difficulty, even by experts, during the earliest period of infancy, and even at the school age the exact degree of disqualification is not readily determined; it is with the view of affording

[1] HISTORY.—Perhaps the first case of Raynaud's disease was recorded by D. D. Hertius in the year 1684, in a note entitled, "De Ardore manuum ac pedum intolerabile," published in Miscellanea Curiosa, Academiæ Naturæ Curiosorum, Annus Tertius, Nurembergæ, 1685. Obs. civ., p. 203. Dr. Hertius says that he was called to see an unmarried woman, twenty-six years old, who was daily afflicted with a most intolerable burning or heat in the hands and feet, which yielded to no remedies. She finally was made so desperate by her sufferings that she would keep them in the coldest water. Eventually, gangrene of several of the toes and fingers set in. The gangrenous parts were amputated, and the patient finally recovered. Dr. Hertius, in the form of a "Scholium," gives a learned disquisition upon the pathology of this affection, but he throws no light upon it.

The subsequent history of the discovery and description of Raynaud's disease and its allied forms is of some interest.

A case resembling it was described by M. Bocquet in the Journal de Corvisart, 1808, t. xvi., p. 283, and referred to by François in an Essai sur les Gangrenes spontanées, Paris, 1832. A disease resembling local asphyxia was also described by Brodie in his Lectures on Local Nervous Disorders, 1837; also by Huston in 1836.

A disease more of a vaso-paralytic and neuralgic character, like erythromelalgia was described by Graves in the Dublin Journal of Medical Science, 1840, p. 257, 259, and in the Edinburgh Medical and Surgical Journal, 1849, lxxi., p. 238. In 1862 M. Raynaud (Thès. de Paris, 1862) gave a very complete description of the trouble, which he described as a local asphyxia of the extremities, of nervous origin, ending sometimes in gangrene or in slighter trophic disturbances. In 1872 (Nouveau Dict. Méd. et Chir. prat.) and in 1874 (Arch. Gen. de Méd.) he wrote of the disease again. Meanwhile many other observers have contributed facts and observations regarding it, viz.:

Nothnagel, in 1866, and Esslander, in 1870 (vid. Nouveau Dict. Méd. et Chir.).
Rey, 1869 (Arch. de Méd. Naval, 1869, p. 211).
J. R. Pigg (Lancet, 1870, vol. ii., p. 397).
Mourson, 1873 (Ibid., p. 364).
Allan McL. Hamilton (N. Y. Medical Journal, 1874, October).
Fischer (Arch. f. klin. Med., xviii., 2, 1875, p. 335).
Calmettes (Gaz. Méd., 1876, 44, p. 520).
Armaingand (Rev. Sc. Méd., x., 548), occurring in hysteria.
Lereboullet (Soc Méd. Hop., March 22, 1878), occurring in brachial paralysis (Gaz. Hebd., 1878, 13).
Grasset and Apolinard (Grasset's Mal. de Ner. Syst., vol. ii., p. 244); occurring in brachial paralysis and scleroderma (Montpel. Méd., 1878).
Dr. T. A. McBride (MEDICAL RECORD, May 11, 1878), cases of digiti mortui.
Dr. S. Weir Mitchell (Amer. Jour. Med. Sci., July, 1878), describes erythromelalgia.
Dr. Chas. K. Mills (Amer. Jour. Med. Sci., October, 1878).
Bernhardt and Schwabach (Rev. Sc. Med., viii., 274).
Rapin (Ibid., viii., 275).
Wynn Foot (Ibid., ix., 225).
Dr. R. Southey (Tr. Clin. Soc. of London, vol. xvi., p. 167; St. Barthol. Hosp. Repts., vol. xvi.)
Barlow (Tr. Clinical Soc., vol. xv., p. 167, 1879).
Mr. Thos. Smith (Ibid., 1880).
M. Mourson, 1880 (quoted in Rev. de Chir., 1883, p. 5), digiti mortui of malarial origin.
Quinquand (La France Médicale, Sept. 6, 1881, p. 325), a form between erythromelalgia and scleroderma.
Weiss, of Prague (Zeitsch f. Heilk, 1882, vol. iii., p. 233).
Hastreiter (Wien. Med. Presse, 1882), twenty-two cases.
Mommsen, July, 1882 (Boston Medical and Surgical Journal, cix., p. 250), twenty-one cases.
Hélye (De la Malad. en. Algerie, p. 51), digiti mortui of malarial origin.
Petit and Verneuil (Rev. de Chirur., 1883) collect a number of cases illustrating the paludal origin of Raynaud's disease in its mild and gangrenous forms.
Dr. Lauer (Thès., Strasburg, 1884), two cases of Raynaud's disease.
Dr. Woodnut (Medical News, December 27, 1884, p. 717), case of erythromelalgia.
Dr. Colcott Fox (Lancet, May 30, 1885, p. 990), Raynaud's disease, with gangrene.
Dr. W. W. Johnston, in the American Journal of Obstetrics, April, 1885, p. 393, under the head of a Rare Form of Vaso-motor Neurosis, records a case of Raynaud's disease.

The cases reported are, for the most part, cases of local asphyxia or digiti mortui; others are illustrations of local asphyxia with symmetrical gangrene. Barlow and Petit and Verneuil, as well as Raynaud, give good cases of this kind. In still fewer instances the symptoms are more like those of erythromelalgia.

[2] Presented to the International Congress of Educators, New Orleans, 1885.

some aid to parents and teachers in this regard that this paper is written. In order to enhance the practical value of the views advanced, I have availed myself of notes that have been taken during an extended experience in the examination and treatment of the aurally defective.

The 450 cases of children's deafness selected as illustrative, are from among children seen in private and infirmary practice, and they represent almost every variety of disqualifying deafness. The defective pupils among this number were brought to me from both hearing and deaf-mute schools. A considerable number of these constitutes a class not properly provided for in either, being too deaf for hearing schools and yet not deaf enough to be taught as deaf-mutes; they were, therefore, found to be oscillating, shuttlecock-like, between the two, liable to be cast forth into life with much less education than their intelligence entitled them to receive —usually with scarcely intelligible articulate speech.

On account of their instructiveness, I have included in the cases above selected a few not strictly of the school age.

The cases may be divided into two groups based on their school status; thus 371 were attempting to retain their position in hearing schools, whilst 79 were either so deaf as to be excluded or were not of the school age.

The first group of 371 was constituted as follows: 74 were between five and seven years of age; 200 were between eight and twelve years of age; 97 were thirteen years of age and upward. As to sex, 199 were females and 172 were males. The causation in these cases could be traced to either purulent or non-purulent inflammation of the ear-drum (tympanum). In 219 cases it was the former, and in 124 cases the latter.

Usually both ears were similarly affected in each case, but where a purulent affection existed on one side and non-purulent on the other, the case was classed with the former. In the non-purulent cases both ears were almost without exception similarly affected, although the left ear was usually the worse of the two.

Belonging to either one or the other of the above varieties were 10 cases where the ear had been severely boxed or pulled, causing rupture or strain of the drum-head, and consequent deafness; 33 cases where cold sea-water had passed from the mouth up into the drum through the Eustachian tube, while the child was bathing in the ocean; 3 where water was introduced into the drum while sniffing it up into the nose, or in using the nasal douche. In 31 cases the cause was attributed to scarlet fever, in 17 to measles, in 5 to diphtheria, in 4 to whooping-cough, in 1 to mumps, and in 1 to syphilis.

The external auditory canal was obstructed in a number of instances, thus interfering with the entrance of sound; in 52 cases it was by wax, in 7 by foreign bodies, in 25 by narrowing of its walls by inflammation. Among the last named were 8 cases where the canal was ulcerated.

The drum-head gave evidence, on examination being made by reflected light, of defectiveness of the transmitting mechanism in a considerable number of cases. Thus, in 30 there was deformity of the membrana tympani from perverted development; in 27 cases there was greater or less destruction of the mechanism from suppurative inflammation; a polypoid growth sprung from the morbid tissues within the drum in 14 cases, and the inflammation extended from the drum to the pneumatic cells of the mastoid in 8 cases.

It is noteworthy that defective teeth were present in nearly every case, and 189 of them were specially bad. Head-catarrh and enlarged tonsils were present in the greater number, and in 13 cases either the nasal passages were so much obstructed, or the teeth so malformed, that mouth-breathing was habitual.

The affections thus far mentioned are those which interfere with the passage of sound to the middle ear and its transmission to the inner ear, but the deeper parts containing the distribution of the auditory nerve may, in the more severe cases of ear-disease occurring from scarlet fever, diphtheria, etc., be attacked at the same time. In 28 of these cases, it may be incidentally stated, either tumors, or abscesses, or wounds of the auricle from piercing for rings, were observed. Distress from the autophonia of ear-disease, the autophonous perception of voice and sounds arising from the performance of physiological functions of the circulation, respiration, and swallowing, were present in 41 cases, and dysacousma was present in 1. Pains in the ear (otalgia) were experienced by 28, pains in the aural region (neuralgia) by 36, ear-cough by 10, epilepsy by 1, vertiginous symptoms by 18, chorea by 2, and various other reflex phenomena by 17.

In respect to the degrees of deafness, 113 were almost totally deaf, while the remaining 258 were all of them incapacitated in some degree from receiving instruction at school along with good-hearing scholars.

The second group of 79 cases was composed mostly of so-called deaf-mutes; 38 were under five years of age, 21 between five and seven, 11 between 8 and 12, and 9 thirteen and upward. There were 41 females, and 38 males. Of this group, 18 were recorded as congenital deaf-mutes, but the diagnosis was in some of them considered doubtful; in 25 cases the trouble was traced to cerebral meningitis, in 19 to purulent inflammation of the drum, and in 17 to non-purulent inflammation of the drum.

In regard to their aural defectiveness, 26 of them were found to hear well enough to be taught *aurally* by the aid of a conversation-tube, or by using the voice close to the child's ear in teaching; 2 of them, although totally deaf, attended school along with hearing pupils; 4 of them retained speech after losing their hearing, and this without the aid of a teacher, and one of this number continued to use the English cockney accent which he had acquired before becoming deaf; in 17 cases the children were losing the speech they had acquired before becoming deaf, or were very defective in this regard from neglect to teach them. The younger children composing this last-mentioned class were nearly all of them backward in learning to talk; one of them did not acquire speech until his good-hearing brother became old enough to converse with him, and another did not talk until five years of age. Seventeen patients had never learned to talk, and a considerable number of these were considered mentally defective, solely on account of this defect, by their parents or teachers. In one case it was noted that the impact of sounds was painful (dysacousma).

It will be observed that in the greater number of all of the cases above presented, the cause of aural defectiveness was attributable to some inflammatory affection of the hearing organ. Thus *cerebral meningitis*, occurring in connection with children's diseases, contributed largely to this list; its invasion is always sudden, and it generally causes bilateral deafness. It does not give rise to running from the ears. Meningeal inflammation is usually meant when pachymeningitis, cerebro-spinal meningitis, brain fever, cerebral meningitis, convulsions, fits, and the like, are mentioned in this connection. Sometimes the symptoms of irritation of the stomach are so marked in meningitis that the case has been erroneously regarded as "gastric fever." Inflammation of the ear-drums, whether purulent or non-purulent, acute or chronic, leaves characteristic appearances which are easily recognizable. Among the smaller number there were some where the precise nature of the origin of the difficulty was obscure; following the usual custom, the writer, tentatively, relegated these to the somewhat vague realm of the congenitally deaf. Subsequent experience, and a more particular study of the subject, seem to show that in some of the instances of supposed deaf-born children, the disability should be assigned to extra-uterine causation.

Thus cerebral meningitis affecting the nerve of hearing, and suppurative inflammation of the drum of the ear af-

fecting the transmitting mechanism, consecutive to children's diseases, as scarlet fever, measles, and diphtheria, are frequently met with at the period in life when children are learning to talk, and the more carefully these patients are examined in this regard, the more frequently will it be found that deafness was first discovered to exist subsequently to some attack of this kind. In eliciting from parents the history of these cases, one should not place too much value on alleged injury to the ears from falls and blows on the head, which are often advanced as causes.

Acquired deafness.—Conditions favoring early deafness are not wanting—indeed causation may antedate or be encountered at birth, since at this period the drum in a normal state contains no air, but is filled with loose œdematous connective tissue, which slowly disappears when aëration of the cavity takes place with the establishment of the respiratory act, the cries, and the performance of deglutition by the infant. When action of the upper respiratory tract is defective, as it may thus be at birth, or, soon after, by head catarrh or by aural catarrh, the necessary aërial equilibrium is not established, and oscillations of the transmitting apparatus cannot take place. Under these circumstances the perceptive function lies dormant because it cannot be aroused to normal action.

Congenital deafness.—A tendency to propagate constitutional dyscrasias doubtlessly exists in some persons, and when predisponents to catarrh are active in such a case, hereditary catarrh may give rise to disease of the ear at the earliest period of life. This hypothesis is borne out by clinical experience. I have at the present time under treatment for aural catarrh a bright little lad three years of age, who cannot yet talk on account of this defectiveness. His mother informed me that she was exceedingly susceptible to head catarrhs, and the grandmother is so deaf that she has to carry about a conversation-tube. I was much impressed by these cases, and was even surprised when informed that my patient's great-grandmother was very deaf.

The possible effect of influences on the maternal progenitor are worthy of consideration. The following case in this connection is suggestive: The first-born child of a healthy, well-developed, and intelligent woman was, when six months of age, thought to be deaf, since she could only hear jarring of the floor and the like, and the sound of a high-pitched whistle which her father carried, and which seemed to become quite familiar to her ears. The mother had, however, during the first month of pregnancy an attack of rubeola, or German measles, and was, furthermore, much worried during the entire period of gestation about her husband, who was very nervous and becoming deaf from aural catarrh. When I examined this child at the age of sixteen months, it was found to have catarrh of the head and ears, the origin of which may have been embryonic. No anatomical malformation of the ears was discovered in the infant, nor was there any apparent transmissible organic defect in the parents.

Deafness due to congenital anomalies of the auditory apparatus.—These are supposed to be traceable to some perversion of development during the morphological state. The hearing organ in man has both an intracranial and extracranial origin, one centric and the other peripheric. From the auditory vesicle which constitutes the centric is evolved the nervous, or perceptive tract of the ear, while the first visceral cleft evolves the peripheric, or outer structures comprising the transmitting apparatus, namely, the Eustachian tube, the drum, and the external auditory canal and auricle. Now during the embryonic or fetal states, any interference with the development in either of these regions would produce defects in the hearing organ. Evidence of developmental defects is not always obtainable, and where the trouble is centric a diagnosis cannot be made in the very young, for obvious reasons. Evidences of peripheric defects, however, are by no means rare; these consist, for the most part, in either defective or excessive development in the closure of the first branchial cleft, the most common form of which is *fistula auris congenita*. The presence of these anomalies is very likely to be overlooked. In the following typical example they were not observed until several examinations of the ear had been made, their existence not being suspected at first: The case was that of a child of eight years of age. She was thought to be defective in intelligence until she was two years of age, since she did not learn to talk; but she grew more intelligent in appearance, and it was then found that she was deaf. When four years old some person undertook the task of instructing her during a long sea voyage, and she learned to spell and pronounce a few words. When five years old she was sent to the public schools in New York, and had made considerable progress up to the time when she was brought to me Examination of the hearing showed that she could not understand conversation in any tone at the distance of a few feet; but when her name was spoken in a smart tone she would promptly look at the speaker. She can hear the voice quite distinctly when the speaker is only a few inches distant. The teacher, for some reason, requires her to sit in the farthest seat from her desk. A minute fistulous opening is to be seen on the front part of both auricles, from which a small quantity of offensive fluid issues spontaneously at times, and usually on the right side, when the parts are pressed by the fingers. The external auditory canals are of the normal size, but the drum-heads are somewhat defective in appearance, the membrane being puckered at its anterior superior quadrant.

I have seen a very considerable number of these cases in adults, always where hearing was defective, and although generally unilateral, it is probable that in nearly all cases some degree of defectiveness exists on both sides. It seems probable that, where centric malformation exists, co-existent mental defects are liable to obtain, and we should, therefore, expect to find imbecility as well as deafness.

In the treatment or education of deaf children it is well to keep in mind the fact that defectiveness is not always absolute, and may, therefore, be amenable to treatment on the one hand, while not constituting an insuperable barrier to aural instruction on the other.

It would seem that the neglect of deaf-born children, in the lower order of social life, much more frequently results in dumbness than would occur if more pains were taken in their education; indeed, where the offspring of deaf-mutes are constantly surrounded by deaf-mutes holding converse with each other by signs only, it would be strange if they should learn to talk unless possessed of good hearing and allowed to associate with speaking persons. If children with defective hearing organs have but little, if any, opportunity to employ them, it is probable that continuous disuse of the sensory tract would finally lead to its deterioration. A child brought up under unfavorable conditions in this respect would acquire the use of the voice with difficulty, if at all, since even where normal hearing exists and favorable opportunities are afforded for learning, it is only after long and patient practice that intelligible speech is acquired.

The difficulties that beset partially deaf children where the defectiveness interferes with school instruction, admit of much easier interpretation than those of very young children. As regards the latter, inquiries as to causation are liable to be met by vague, unreliable, and even misleading statements, and the truth can only be reached by painstaking, eliminative analysis. Parents thus offer some entirely irrelevant accident, as an injury from a fall or blow, or an inconsequent trouble, as vaccination, or illness not affecting the ears, as causal, where examination often shows, after all obscurities have been put aside, that aural catarrh is the sole cause of the trouble, or that the case is congenital. It seems to offer

the ignorant much more satisfaction, in many instances at least, to regard deafness as a calamitous visitation, to account for which a striking catastrophe is required, rather than any natural, though much more simple, cause.

The dumbness of deaf children by no means always bears a constant relation to their aural defectiveness; a child intellectually bright, with favorable opportunities for learning, will make much more rapid advances than a child mentally dull and neglected. The writer has met with numerous examples where totally deaf persons obtained an excellent education in private hearing schools; they have been, of course, attentive and quick to learn, and special attention had been given them by teachers. This courageous achievement has been limited to the gentler sex, so far as my own observations have gone.

Dysacousma.—The painfulness of sounds to the perception of some deaf people is extreme. This is probably due to the sudden and unusual transmission of sounds which are felt at the perceptive centre as a shock. The low rumble of thunder, or the deep tones of an organ, are unbearable to some deaf persons, while others cannot endure a whispered sound when made directly into the ear.

If a medical writer might venture to offer a suggestion in pedagogics, I would urge early attention to home instruction for deaf children. Hearing children naturally pick up their earlier education without effort from parents or by themselves, but deaf children must be unremittingly taught at close range; words must be uttered directly into the ear, not loudly, but distinctly. Tubes are of value in conducting sound to the child's ear where close contact of the mouth is inconvenient, and the child should be encouraged to repeat its own words through the tube to its ears so as to compare its own voice with the instructor's. If this course be pursued early enough, I am convinced that but few children would be found without *any* hearing sense, and many who have considerable hearing likely to be lost from disuse would gradually be improved.

The greatest difficulty encountered at first is in overcoming inattention on the part of deaf children, who are disposed to rely on the sense of vision, since it offers so much easier a method of conversing. Much time is lost, I am convinced, from neglect to insist on this matter.

Where it is possible to avoid doing so, a deaf child should not be taught alone, but placed in company with hearing children. Instruction at school could with advantage be commenced much earlier than is done at present; some children are as capable of attending school when only three or four years old, as are others at a much more advanced age. Deaf children might, indeed, be made an exception of in regard to school age, since their training should begin so much earlier than hearing pupils. Where deafness has occurred after the pupil has learned to talk, unsparing efforts should be made to aid him in retaining this faculty, otherwise dumbness may result.

Olive-oil as a Menstruum for Dissolving Cocaine for Application to the Eye.—Dr. Joseph A. Andrews, of New York, writes: "In addition to the occasional benefit derived from the use of oil dropped into the eye in recent abrasions from burns, and in other painful affections of the cornea in which atropia is indicated and cocaine may likewise be serviceable, the plan of dissolving the cocaine in oil seems to insure a longer contact of the remedy, and a smaller quantity is required to effect anæsthesia. Neither the salt of cocaine nor that of atropine is soluble in olive-oil, but the alkaloid dissolves readily in this menstruum without the addition of alcohol, it being only necessary to expose the solution for a few minutes to a gentle heat in a water-bath. Castor-oil is not a desirable menstruum on account of its irritating qualities; and the oleate of cocaine, for the same reason, is still more objectionable as an application to the eye."

CHOLERA.

By MANKAN G. DADIRAIAN, M.D.,

NEW YORK, FORMERLY OF CONSTANTINOPLE, TURKEY.

The cholera has been a great terror in this century, both among civilized and uncivilized nations. My intention in this article is to glance at the three following points:

First—How to escape it?

We see a prevailing belief in the minds both of the profession and the laity that the disease will surely visit New York this year. It may come, but it is hardly probable. Cholera may travel in three different ways: by human intercourse, by baggage—furniture, etc.—and by the air. Strict quarantine may prevent the spread of the disease by the two first-named agencies. The air is to be regarded as dangerous only for short distances.

The great benefits of quarantine can be explained by relating the circumstances concerning Constantinople:

Whenever cholera has appeared in Egypt or in Europe, it has always later appeared in Constantinople. Unfortunately, there has always prevailed in Turkey the belief that all plagues are scourges sent from God to punish human creatures and correct them. Therefore, it is not wise (say the people) to use any measures to ameliorate or prevent this punishment. "It is provoking the Almighty." Hence, though a show of quarantine has been kept up to distract the attention of the other European powers, passengers have been allowed to land without any precaution being taken; and, in its practical bearing, the whole thing has been a farce.

When the cholera was raging in Egypt, in 1883, the population of Constantinople was in great terror lest the disease should break out in their midst. All persons having diarrhœa were alarmed, and, contrary to their usual custom, at once sought medical treatment, thinking that the dreaded malady was upon them, and, in fact, many of the cases had a decided choleraic appearance. At this time the sanitary condition of the city was as bad as could well be imagined, but neither in that year nor the year following did cholera appear, though it was travelling along the Mediterranean shore, in Spain, France, and Italy. Why did it not visit the city in these years? For the following reason:

The present Sultan, Abdul Hamid, is an entirely different sort of a person from his predecessors. He believes that not only plagues, storms, earthquakes, etc., come from God, but that all insects, etc., come from Him: hence, he reasons, if we kill and drive away the latter, why should we not do all in our power to ward off the former. So he established a strict quarantine, and kept his palace in telegraphic communication with the quarantine stations, and in every way contributed to the efficiency of the service, rewarding faithful and punishing unfaithful subordinates. He even arrested some rich merchants who had evaded the watchfulness of the quarantine officers and violated the health laws. If the watchfulness of the Sultan has done all this, will it not be possible for the United States to be as careful as Turkey has been?

Second—What are the proper prophylactic measures during an epidemic?

They are simple, and can easily be followed out by all classes of people.

1. All rooms should be thoroughly aired and ventilated; also whitewashed. The utmost cleanliness should be maintained, particularly in halls and on stairways.

2. As few people as possible should sleep in the same room.

3. Bathing should be practised regularly.

4. Great regularity in eating should be followed. All salt and fat meat, salt fish, sausages, and raw fruit should be avoided. The Turkish Government exercises a rigid supervision over the sale of fruit, and all that is condemned is thrown overboard. Imprudence in the

use of fruit is one of the most prolific causes of the disease.

5. Great moderation in beverages is necessary. If possible, all stimulants should be avoided. A little wine with water is occasionally allowable. Ice-water and much ice itself are injurious. All water for drinking purposes should be boiled from ten to thirty minutes, and then passed through a filter containing several pieces of charcoal. Fermented milk is a valuable food, and stimulant as well. The writer presented a specimen of that used in Turkey at a recent meeting of the Academy of Medicine. Its acidity has a direct prophylactic effect, even after exposure to choleraic influences.

6. Both the mind and body should be kept in a healthy condition. Particular caution is necessary against excessive exertion, followed by sweating and subsequent exposure to cold in any form. No one should lie down or sleep before an open window.

Those who follow these directions rarely experience the disease. It is true that the percentage of mortality among those attacked is large, but the aggregate population should be reckoned in. The epidemic of pneumonia here in New York last winter carried off many, but they were those who exposed themselves to cold and severe weather. Some were too poor to properly protect themselves; others were careless for the sake of interest or pleasure. So with cholera. If you once contract it, the situation is alarming; but with proper precautions the chance of contracting it is not one in one hundred. And even after the disease has set in, it can generally be checked if prompt treatment be at hand.

To illustrate this point, the case may be cited of two hundred Armenians who went last year from Constantinople to Marseilles, where the cholera was then raging. These people were all well-to-do. Most of them had already seen several epidemics in the former city, and knew how to protect themselves and their children. Not one contracted the disease in their new residence. That most estimable gentleman, Dr. Cyrus Hamlin, who spent forty years in Constantinople, and who had a wide and interesting experience in different epidemics, says in his book: "If you prepare for it (cholera), it will not come. I think there is no disease which may be avoided with so much certainty. But providential circumstances, or the thoughtless indiscretions of some member of a household, may invite the attack, and the challenge will never be refused." The greatest danger lies in the contact with choleraic discharges. This danger is greater than that of contact with the patient himself. To avoid this danger the stools should be thoroughly disinfected, and the closets where they are emptied should receive a thorough charge of the disinfecting agent. The disinfectants that are always kept in the houses of Europeans residing in Alexandria are as follows: First, two parts of carbolic acid and one hundred parts of water; second, twenty parts of ferrous sulphate and one hundred parts of water; third, one part of chloride of lime and eight parts of water. Either one of these may be mixed with the dejecta in the proportion of one to ten, and greatly diluted with water for urinals and closets.

Third—The treatment of cholera. Without entering into the pathology and symptomatology of the disease, herewith is given the most simple and practical method of treatment which has yielded good results in Constantinople and Asia Minor. There are four stages of cholera, requiring each a more or less different treatment: (*a*) Choleraic diarrhœa; (*b*) true cholera, with rice-water discharges; (*c*) collapse; (*d*) reaction.

(*a*) Choleraic diarrhœa. This is the most important stage to be taken into consideration. At the first appearance of this symptom, treatment should be begun. Many are careless about the matter, and forfeit their lives in consequence, for this is the time when treatment is most efficacious. Sometimes this stage lasts one or two days; again only two or three hours, and then the succeeding stages follow with fearful rapidity. The patient must remain at home, stop his regular eating and drinking, and take as follows:

℞. Chloroform,
Laudanum.....āā ʒ ij.
Brandy..... ʒ iijss.

M. Sig.—One tablespoonful every two to three hours in water.

One dose will often stop the diarrhœa, but it is safer to continue the remedy in half doses until the next day. This is the method mostly used in the English Army in India. In Turkey, however, another mixture is generally used—known as "Dr. Hamlin's," as this gentleman introduced it in 1848 with great success. It consists of equal parts of laudanum, spirits of camphor, and tincture of rhubarb. Thirty drops of this mixture may be given in a little water, or on a lump of sugar. The diarrhœa is generally checked, and great relief is also given to the vomiting and colicky pains which are often present. The dosage may be doubled if necessary. This remedy also should be continued for a day or two in gradually diminishing dosage. The diet should be rice, soup, toasted bread, and fermented milk (matzoon).

(*b*) True cholera. Here we find cramps, colicky pains, vomiting, and diarrhœa. The stools may succeed each other at intervals of from ten minutes to several hours. In India calomel is used in this stage, in hourly doses of ten grains, till the stools present their normal color and odor. This remedy is not much used in Constantinople, where "Dr. Hamlin's No. 2 Mixture," as it is called, has worked charmingly. It consists of equal parts of laudanum, tincture of capsicum, tincture of ginger, and tincture of cardamom seeds. Dose thirty to forty drops in a little water, given after each movement. After the third dose both the diarrhœa and vomiting are usually stopped. In this stage sinapisms must be applied to the stomach, abdomen, calves, and feet. Diet: rice-water, crust wafers, chamomile tea.

(*c*) Collapse. Here spirits are our only sheet-anchor. Brandy or whiskey may be given every half hour in tablespoonful doses. Sinapisms, hot bottles, etc., are useful. The condition is one of the greatest gravity, but by no means hopeless. Many are pulled through.

(*d*) Reaction. As soon as the patient rallies, the treatment must be carried on entirely on general principles. After reaction has fairly set in, great care must be taken to prevent a relapse or a typhoid condition, which may prove fatal.

334 East Seventeenth Street.

Hot-water Applications in Hemorrhoids.—Dr. W. H. Bryant, of Savannah, Mo., writes: "In The Medical Record of May 9, 1885, Dr. Bennett gives a short article on the use—or rather abuse—of hot water in hemorrhoids. He makes no reference, however, to its local use, but refers to the popular custom of drinking hot water before breakfast. Many years ago it was the custom with all physicians to direct their patients suffering from piles to use ice or ice-cold water as a local application. Of late years I have been constantly using hot water as a local remedy, and find the relief is not only prompt, but a speedy cure is the result in every case in which I have used it. My attention was first directed to the use of hot water in the treatment of local inflammation by observing the benefit derived from vaginal irrigation as practised by Dr. Bennett in pelvic inflammations. The method of using the bath for either external or internal hemorrhages, is to direct the patient to sit over a bowl containing the water, as hot as the hand will bear, and with a soft cloth alternately dipped in the water and applied firmly to the anus. This should be continued for ten minutes, and repeated as often as every four hours. The first application gives prompt relief to the smarting and burning pain; twenty-four to thirty-six hours is sufficient to complete the cure."

WIRING OF FRACTURED PATELLA.

By FRASER C. FULLER, M.D.,

NEW YORK.

THE infrequency with which this operation is performed in this country, as compared with its performance on the other side, and in Great Britain especially, is sufficient excuse for the report of an individual case. Patellæ have been wired by several prominent surgeons in this city within the past year, and with excellent results, but as far as I know have not been reported in the journals as yet.

The case about to be described forms the fourth operated upon by the writer (for notes of first three cases see THE MEDICAL RECORD, December 22, 1883), and all have been eminently satisfactory, both in immediate and in later results, *i.e.*, no especial constitutional disturbance from the operation, primary healing of the soft parts, bony union of the patella, and complete retainment of function of the joint. The patient, G. S——, twenty-two years of age, was one in the practice of Dr. Moir, of Union Hill, N. J. He was a professional athlete. On March 15th last, while exercising on a horizontal bar, on jumping to the floor, he miscalculated the location of the padded mat beneath the bar, jumped upon its edge, his heels resting upon the mat, his toes upon the floor. It will be seen that the fracture occurred from muscular action. I saw him the next day, twenty-six hours after the accident, and proceeded to operate.

A transverse incision was made, the joint cavity cleared of fluid blood and blood-clots, and the thick, leather-like clots scraped from the bone-surfaces. Two sutures of silver wire were used for the patella, one seam of catgut for the joint capsule, another for the integument; one rubber drainage-tube was employed. It was not found necessary to ligature any blood-vessels. An ordinary dressing of iodoformized gauze and antiseptic cotton was employed, and a splint of wire netting. The limb was suspended and the foot elevated. The dressing was changed on the thirteenth day, and the tube removed; dressed again on the twenty-eighth day, and the soft parts found healed. Patient allowed to walk at the end of seven weeks, and he has now complete use of his limb, with almost entire return of function in the joint.

259 WEST FIFTY-FOURTH STREET,
June 15, 1885.

VACCINATION AND INOCULATION.—At a recent meeting of the London Society of Arts, Dr. Robert Pringle, surgeon-major in the Bengal army, read an interesting paper on the "Ancient and Modern Methods of Treating Epidemics of Small-pox in India." The ancient method was the practice of inoculation, the modern that of vaccination. Dr. Pringle's observations have extended over twenty years. He said inoculation had been practised in India from time immemorial. The virus had, however, become attenuated by passing through many transmissions until the cultivated product resembled in its action cow-pox lymph, and caused only local symptoms at the part inoculated, and a small-pox eruption only exceptionally. The speaker said vaccination in India differed considerably from that in England. It could be practised only during the five cooler months of the year. Comparing inoculation with vaccination, he said that while the former kept up small-pox, it was nevertheless a boon to the population. It could be practised throughout the year, and need not be repeated as vaccination is. Dr. Pringle did not advocate revaccination—at least, he did not practise it. In his sanitary circle, with a population of ten millions, with two hundred operators working solely at vaccination for five months, it was impossible to reach a number equal to more than half the birth-rate. He therefore discouraged revaccination, and made quality and not quantity the basis of his work.

THE REPORTS OF THREE CASES OF WIRED PATELLAS.

By ROBERT T. MORRIS, M.D.,

NEW YORK.

THE three cases here described were operated upon by me in the winter of 1883–84.

CASE I.—P. C——, a strong and active fellow, twenty-seven years of age, fractured his left patella by muscular violence in 1872. He fractured his right patella by muscular violence in July, 1883. In December of the latter year he again, by muscular violence, separated the fragments of his right patella, tearing the fibrous band of connection. The patient walked two and a quarter miles after receiving this last injury.

All of the breaks referred to above happened as the patient struck on his feet after jumping from his carriage.

On examination, I found that the fragments of the left patella were two in number, of about equal size, and that the fracture was a transverse one. The fragments were separated by a distance of four inches when the knee was flexed, and a thin, strong, fibrous band extended between them. The patient believes that this leg, in this condition, is just as useful as it was before the injury.

On examination of the right knee-joint I found the ordinary results of such an injury as the knee had received. The two fragments were of nearly equal size, and were three-fourths of an inch apart. The fracture had been a transverse one.

In another similar case I should not wait for the swelling and inflammation to subside before operating, but here it was thought advisable to apply ice-bags and a posterior splint for a few days.

Eight days after the injury, the symptoms of inflammation having left the joint, operative procedures were resorted to. Working with scientific antiseptic precautions, I made a five-inch incision transversely across the knee, and opened up the joint widely. The ragged ends of a thin, torn ligament showed the character of the injury which had succeeded insufficient repair. The face of the lower fragment looked forward. The fibrous tissue which had united the two fragments was cut away, and a thin, dense layer of new bone removed from the faces of the two fragments. I then drilled two holes in each fragment, entering the drill at the upper margin of the upper one and at the lower margin of the lower one, and made the drill emerge at the junction of the bone with the cartilage on the fractured surfaces. Stout silver wire was passed through the drilled holes, and the fragments approximated as well as possible.

The cartilaginous surfaces touched each other, but the bony surfaces would do nothing of the sort; so I contented myself with twisting the wires together and then uniting with catgut the margins of fibrous tissues which hung over the edges of the little chasm.

A counter-opening into the joint was made at a point situated just above and in front of the point of attachment of the biceps tendons. A catgut drain was inserted into this lower opening, and at each angle of the upper opening a medium-sized rubber drainage-tube was employed.

Three lines of catgut sutures closed the wound. All blood and synovial fluid was washed out of the joint with 1–2000 bichloride of mercury solution.

Iodoform, Lister protective, bichlorided gauze, and an anterior plaster-of-Paris splint were employed in their respective order.

The limb was then suspended and elevated.

No inflammatory reaction followed the operation.

The patient's temperature went to 101¼ F. on the day after the operation, but after a purgative had been given the temperature fell to normal, and stayed there until the wound had healed.

Twelve days after the operation, the dressing was changed for the first time and the two rubber drainage-tubes removed.

Primary union had united everything, except at one part of the skin-wound where the suture had slipped.

The dressing was changed with scientific antiseptic precautions, and the same material used for the second as for the first dressing.

Eighteen days after the first dressing the second dressing was removed and the fragments of the patella found to be firmly united. A splint was applied, and the joint kept at rest for about six weeks longer, passive motion having been made three or four times within this period.

No pus was found in either the first or the second dressing, and the few drachms of thick gelatinous discharge showed no sign of decomposition.

The patient began gradually to use his knee, and walked with a cane for several weeks.

More than a year has now elapsed since I last saw the man, and my efforts at finding him have been unsuccessful. To an acquaintance of mine, however, who recently met him, he said that the knee was perfectly well, and that he considered it to be as good as it was before the patella was broken.

The silver wires remain in place.

The union is probably fibrous, because the bony surfaces of the fragments could not be closely approximated.

At the time of operation it was hard to decide whether to cut through the quadriceps muscle, in order to allow the upper fragment to be carried downward, or to cut the patellar ligament, and allow the lower fragment to be pulled upward, or to unite the fibrous tissues about the patella, and trust to the getting of fibrous union—the bony surfaces at the point of widest separation being less than one-fourth of an inch apart.

The latter course was followed, and evidently with good results, but a case which I have since seen would bend me toward cutting the patellar ligament for the purpose of allowing the lower fragment to ascend in case it were impossible to get the fragments into close relation with each other without so doing.

The case in question is briefly as follows: Several months ago, a Mr. L——, of Connecticut, a Yale student, accidentally cut into his knee-joint with an axe, the cut severing the ligamentum patellæ at its point of attachment with the patella, and allowing that bone to be drawn up above the condyles of the femur. The wound healed, and the ligamenture structures which extend from the sides of the patella to the head of the tibia assumed the function of the destroyed ligament, so that the movements of extension are perfectly good, and the patient complains of the deformity from a cosmetic stand-point only.

Another interesting feature of the case which I may mention here is the fact that the skin which formed the lower margin of the wound is firmly attached by cicatricial tissue to the patella, and when the quadriceps group contracts this skin becomes extremely tense, and aids in flexing the leg by virtue of its close attachment about the tuberosity of the tibia.

The point at once suggested itself to me that in any case in which it is necessary to excise the patella a strip of skin could be turned up from the anterior portion of the leg just below the knee and sutured to the tendinous portion of the quadriceps which had previously been attached to the patella.

This operation, I think, has never been done because the tissues to be sutured together are so unlike that operators have not supposed that a usefully strong union would follow.

The case above-cited seems to open up, therefore, two good points for surgeons.

Case II.—George K——, fifty-two years of age, slipped while walking and struck his right knee against the curb-stone. I saw him a few hours later, and found that he had fractured his right patella transversely. The fracture separated the bone through its middle, and a hazel-nut-sized piece was broken from the lower fragment. The knee was swollen and contused, and extremely painful to the touch. A posterior splint and ice-cap were employed for two or three days, and then the limb was immobilized for a week with a plaster-of-Paris splint. At the end of that time the swelling and tenderness had disappeared to a great extent. The splint was removed and the case operated upon.

My first incision was a vertical one, extending over the front of the knee. This incision not giving sufficient room for working, I made a five-inch-long transverse incision which passed across the knee between the two larger fragments of the patella. A large and firm blood-clot was found between the fragments, and the joint capsule was turned over upon and united to the fractured surface of the lower fragment in such a way that almost no fresh surface was left for the helping out of reparative processes. There then were found two mechanical obstacles to repair. Another obstacle depended on the position of the lower fragment, the fractured surface of which looked forward. A counter-opening was made at the most dependent part of the joint, and the whole joint cavity thoroughly washed out with carbolic acid solution (1 to 40). At the termination of the operation a final flushing of the joint was made with 1 to 20 carbolic acid solution. This last step was a mistake. Don't do it.

The drill was passed through the fragments in the same way as described in Case I., and the silver wires when inserted held the fragments in close apposition. Three lines of catgut suture were used. One layer for the cut and torn capsule, another for subcutaneous tissues, and another for the skin. Drainage was provided for with absorbable bone-drains, and with a small bunch of catgut. The wound was dressed with iodoform, Lister protective, carbolized gauze, and borated cotton. An anterior splint of plaster of Paris and wire gauze was applied, and the limb suspended and elevated.

A few hours after the operation, the patient's temperature arose to 99½° F., but on the following day it was normal, and remained below 99½° F. until the wound had healed.

Two weeks after the operation the dressings were changed for the first time. Everything had united by primary union, but a narrow line of granulations marked the course of the vertical incision. The drains and sutures had been completely absorbed. No pus was found in the dressings. The dressing and splint were reapplied and allowed to stay for three weeks, after which time passive motion was begun. The fragments of the patella had grown firmly together, and the patella as a whole was movable to a moderate degree. The movement of flexion at the knee was, however, very limited, and subsequent treatment by massage, hot and cold douching, tincture of iodine, and passive movement failed to get good motion. The patient at the end of a year is not able to place the right foot on a stair above the left foot.

Why this knee should be so stiff I cannot imagine, as no inflammation followed the operation. Perhaps the strong carbolic acid solution was a factor, and perhaps earlier passive motion would have helped matters. The patient is satisfied with the result, and complains little of his unbendable legability. The wires which remain in the patella have made no demonstration of their presence.

Case III.—S. T——, twenty-six years of age, had strumous arthritis of the left knee-joint. The disease was in its first stage. I felt a couple of cartilaginous prominences in the joint, and behind them to be attached morbid growths of cartilage. I did not know that the disease was strumous arthritis, and opened the joint in the expectation of removing the cartilaginous knobs in question. The latter, however, proved to be normal, and stood out prominently, because the cartilage about them had been absorbed. Finding that the whole surface of the synovial membrane was a mass of vascular fringes, I made a long transverse incision across the knee, sawed through the patella transversely, and then opening

the joint widely, trimmed away the synovial membrane with curved scissors. The lower fragment of the patella seemed to be forward after division of the bone. The patella was wired as the other two had been, and the fragments evidently united by primary union, as at the end of a month after the operation the line of separation could not be found.

Professor Volkmann, of Halle, who has frequently performed the operation just described, tells me that he has never seen a case in which the fragments of the patella failed to unite with complete bony union.

As to the advisability of wiring simple fracture of the patella, I do not wish to express an opinion as yet. There is very little danger connected with the operation, provided that the operator understands some scientific antiseptic method of working. Surgeons who do not work antiseptically will, of course, leave the knee-joint severely alone.

Clinical Department.

ACUTE INFLAMMATION OF THE THYROID GLAND.

A CORRESPONDENT, Dr. C. L. Lang, of this city, sends the following account of a case of this rare affection. A Bohemian woman, thirty-seven years of age, in the eighth month of pregnancy, was attacked with pneumonia. She was delivered of a living child on the second day of the disease, but the course of the pneumonia was favorable, and at the end of two weeks the patient was able to walk about her rooms. The temperature, however, remained from 1° to 2° above the normal, and there was some hectic, but careful examination failed to reveal any mischievous process in the lungs. After a few days she began to complain of pain in an old goitre, which had existed eleven years, and had never before given her any trouble. The inflammatory process went on to suppuration, an abscess formed and opened, and from that time convalescence was rapid and satisfactory. The chronic enlargement of the thyroid gland dated from the birth of the patient's first child, but had not been influenced by any subsequent pregnancies, of which there had been five. It was situated chiefly in the right side of the neck, extending but little beyond the median line. During the period of acute inflammation prior to the opening of the abscess the patient complained of dysphagia and dyspnœa when in the recumbent posture. About four ounces of pus were discharged when the abscess opened.

AN ANTISEPTIC OINTMENT.

DR. M. B. WARD, of Topeka, Kan., sends the formula of an antiseptic ointment which he found very useful while in charge of the hospital department of the Mexican Central Railway. It consists of iodoform, ʒ j.; subnitrate of bismuth, ʒ vij.; vaseline, ℥ ij. This formula was not strictly adhered to in all cases, but was varied according to individual indications. Another formula, suggested by Dr. J. W. Thayer, was iodoform, ʒ j.; boracic acid, ʒ ij.; subnitrate of bismuth, ʒ iv.; vaseline, ℥ ij. The ointment was spread upon a sheet of absorbent cotton sufficiently large to cover the wound and a considerable extent of surface around it. "The dressing seemed to be the best suited to the after-treatment of amputation wounds. It could be removed when necessary with the greatest facility, as it never adhered to the wounded surface. I usually allowed the first dressing to remain undisturbed for from four to six days. There never was present, even in the warm climate of Mexico, the least disagreeable odor, so common when carbolic dressings are used." This dressing was used in over four hundred cases of injuries of various kinds, including ten gunshot wounds and numerous amputations and other capital operations, and of this number there were but two deaths. The writer adds that Dr. J. W. Thayer, of Chihuahua, Mexico, will be pleased to give a detailed account of the results obtained by this method of dressing to anyone wishing the same, as he is in possession of the clinical records.

COCAINE IN THE MORPHINE HABIT.

DR. J. T. WHITTAKER, at the Cincinnati Academy of Medicine, June 29th ult., reported on the use of cocaine in the morphia habit. He used it in a patient who was a confirmed morphia-eater, and had suffered one relapse. He gave ten drops of a ten per cent. solution, equal to one grain. The patient immediately arose to a degree of exhilaration. In one or two hours the uncomfortable sensations returned with as much force as ever. He repeated the injection three times in the next twenty-four hours. In two hours at the outside the desire would return. The patient has now had no desire for the morphia for two weeks. She is loud in her praises of the relief from cocaine. The cocaine gives only temporary relief, yet the Doctor thought it one of the best remedies we have.

Progress of Medical Science.

COCAINE IN VENEREAL AND SYPHILITIC DISORDERS.—The experience of Bono with cocaine in affections of the genital system can be conveniently epitomized as follows (*The Therapeutic Gazette*, June 15, 1885): 1. An injection of a few drops of a two per cent. solution of cocaine removes promptly the pains felt in acute gonorrhœa during micturition and erection. The injection has to remain in the urethra for at least five minutes, and to be repeated four to five times daily. 2. This cocaine injection is unrivalled in rendering caustic injections or the introduction of the catheter painless. 3. The burning pains of blennorrhœa in women yield invariably to small cotton tampons saturated with a two per cent. solution of cocaine, or to the application of a five per cent. cocaine ointment. 4. Cocaine facilitates the examination of urethra and bladder with the bougie and the endoscope. 5. It allows of a painless cauterization in balanoprostatitis. 6. Pointed condylomatæ can be painlessly cauterized, excised, or scraped out with its aid. 7. In cauterization and excision of primary syphilitic affections, cocaine evinced very desirable analgesic virtues of a sufficiently long duration. 8. Taken internally during an antisyphilitic treatment, cocaine did not present any appreciable effects. 9. Its local effects are highly beneficent in syphilitic tonsillitis and in stomatitis mercurialis, and difficulties of deglutition.

FERRÁN'S INOCULATIONS NOT HARMLESS.—A correspondent of the *British Medical Journal* (June 6, 1885), writes from Valencia as follows: "I now come to the most painfully interesting part of my letter, referring to the inoculation by Ferrán and others, and its results. The landlord of the hotel at which I stayed brought to me a lady friend of his, aged thirty-four, very stout and robust, who had been re-inoculated, the last time on May 14th. Her right arm presented a deep erysipelatous circle at least four inches in diameter, in the centre of which a huge phlegmon had formed and burst, and had completely tunnelled through the triceps to the bone, discharging copiously a sanious purulent fluid; the bore of the tunnel was nearly half an inch in diameter; she had violent fever. This case I saw twice, and the last time she was in a sorry plight, her whole arm to the shoulder being in great pain and utterly useless. The second case I saw was the sister of Dr. Serra, chief medical officer of the hospital, brought to me by himself. She had been re-inoculated four days previously, and unbinding the bandage from her painful and useless right arm, I saw, at the bend of the arm, a huge phlegmon, with its large fiery erysipelatous blush, similar to the first case; as yet the phlegmon had not burst. The

third case was a strong healthy woman, who had been re-inoculated, three days previously, in both arms. She was in bed, utterly helpless, with violent fever, both arms enormously swollen, and progressing to suppuration, precisely in the same form and extent as Case I. I was told of many cases which had been similarly affected, and that several had died. I have heard of great numbers being more or less affected in Valencia, in the same way, after the inoculation."

The Value of Cascara Sagrada in Constipation.—At a recent meeting of the Staffordshire Branch of the British Medical Association, Dr. Reid read a paper upon the value of this drug, based on an analysis of thirty-three cases, of which he had taken careful notes. He found: 1, that the result was all that could be desired in twenty seven cases of obstinate and habitual constipation, complicated in many cases by various forms of dyspepsia, and in many people usually of sedentary habits, more especially females; 2, that the effect was most beneficial in three cases of hemorrhoids; 3, that the drug was of no service, even in very large doses, in one case of obstinate constipation, although it did not cause pain; 4, that it had to be discontinued in two cases on account of its causing pain and sickness. The form of drug used was the fluid extract. The conclusions arrived at were as follows: 1. Cascara sagrada was a most useful remedy, both regarding its immediate effects and after-results in obstinate and chronic cases of constipation. 2. It was better to prescribe it in continuous small doses rather than in occasional large ones. 3. Cases were met with in which, even in large doses—at any rate, in the form of the fluid extract—the drug had not been of service. 4. No rule could be laid down by which one could ascertain previously whether the drug would suit or not; but, when pain was produced, in all probability it was owing to too large a dose being given. 5. It was of great service in cases of hemorrhoids when other aperients had failed.—*British Medical Journal*, April 11, 1885.

The Free Use of Caustic Potash in the Treatment of Cancer of the Cervix Uteri.—At a recent meeting of the Medical Society of London (*The Lancet*, May 9, 1885), Dr. Herbert Snow read a paper on the free use of caustic potash in the treatment of cancer of the cervix uteri. He reviewed the statistics of extirpation of the uterus, and showed the severe mortality which followed the abdominal or the vaginal operation. In many cases the écraseur was unable to remove the whole of the disease of the cervix uteri. The actual cautery had too superficial an action to be of any great service. Chloride of zinc caused much pain and distress, which lasted a long period. These objections did not hold with regard to potassa fusa. Half an hour or an hour was recommended to be spent in the employment of successive sticks of potassa fusa, for the treatment must be thoroughly carried out. None of the cases suffered from peritonitis; and unless the patient get up too soon after the operation, nothing distressing need be feared. All the cases were greatly benefited, and no alarming symptoms were encountered. Fixation of the uterus and infiltration of the vaginal wall were regarded as prohibiting the employment of this method of treatment. It was only by degrees that he had ventured to apply the caustic so freely as he now advocated. He illustrated the paper by narrating several cases in which the treatment had been adopted. The object of the paper was to show that potassa fusa could do all that the vaginal cutting operation could perform without running the risk of the severe operation.

Recent Experiments on the Severed Heads of Criminals.—The Paris correspondent of the London *Lancet* (May 9, 1885) writes as follows concerning the above: The question has again been mooted as to whether those who have been decapitated suffer; and after additional experiments on the head of Gamahut, who was guillotined on the 24th ult. for the murder of a widowed lady in Paris, coupled with those related by Claude Bernard, the presumption is that they do, for under the influence of transfused blood the blanched features recovered almost their normal expression, the eyelids were slightly open, and the lips quivered for a few seconds, as if to express some perception communicated from the brain. The conclusion, then, is that, so long as the brain contains any blood, the head of the decapitated person, which falls into a receptacle prepared for the purpose, is capable of seeing, of hearing, and of knowing that it is separated from the body. This view, however, was repudiated by Professor Vulpian at the last meeting of the Academy of Medicine on the following grounds: A strong blow applied to the head, or a less severe one to the stomach, would cause instantaneous syncope; that is to say, consciousness would for the moment be entirely abolished. So it would be in the case of the severed head, but of course without any possibility of recovery; the weight of the guillotine falling upon the neck would produce the same result. Moreover, syncope would be occasioned by the sudden division of the carotid arteries, and the consequent emptying of the arterial system of the brain. Therefore, at the very moment that the brain ceases to receive the vivifying fluid from the heart, it loses all power of excito-motility, as well as all power of sensation; all this transpires as quickly as thought, and its duration may be compared to a flash of lightning. It happened opportunely that a dog that was undergoing some experiments in Professor Vulpian's laboratory was suddenly seized with hemorrhage. Advantage was taken of this circumstance to immediately expose the brain and submit the latter to faradization. Scarcely half a minute had elapsed between the arrest of the circulation and the galvanic irritation. It was impossible to obtain any movements in the legs. The effects of the electricity produced in the muscles of the head and nose were not, according to Professor Vulpian, due to the physiological transmission effected by the brain, but to the neighborhood of the source of irritation; the brain, having lost all power of excito-motility, would in this case act as a mere sponge; and if such a condition was found to exist for only half a minute after the arrest of the circulation, the interpretation put on the effects said to be produced on severed heads by other experimenters must certainly be considered erroneous.

Atrophy of Muscles in Pleurisy.—When synovitis attacks a joint, the muscles which effect the movements of the articulation are prone to waste in a rather rapid manner. The muscular atrophy cannot reasonably be explained on the ground that the muscles are not used, for the atrophy is one which recalls the wasting of muscle seen in cases of infantile palsy, not only in the rapidity with which it occurs, but also in the behavior of the affected muscles to electrical examination. The wasting of muscles of the shoulder and thorax on that side which has been the seat of pleurisy seems to us to belong to the same category of phenomena as the wasting of muscle from joint disease; and although the comparison is a trite one, yet we may remember that serous and synovial membranes are regarded as analogous structures. The subject of muscular atrophy resulting from inflammation of tissues in the neighborhood of the muscles is one deserving of much attention. The most probable explanation is that the abnormal excitations proceeding from the inflamed tissues along the sensory nerves have a direct influence on the motor nerve-cells controlling the nutrition of the muscles concerned: the bones may waste as the result of a similar "reflex" influence. A valuable paper on the atrophy of muscles of the thorax and shoulder in pleurisy was recently contributed to the Société Médicale des Hôpitaux. The author of the paper, M. Desplats of Lille, contends that the muscular atrophy is rapid and frequent in the subjects of pleurisy, that the atrophy plays an important part in the deformities of the skeleton resulting from pleurisy,

and that the atrophy is the indirect cause of tuberculosis of the lungs. He recommends that the atrophy should be prevented from coming on by early surgical treatment of any pleuritic effusion, and that measures should be adopted for arresting or combating the atrophy by the use of general and local stimulants, and more especially by faradization, respiratory gymnastics, compressed air, and so forth.—*The Lancet*, May 7, 1885.

Spontaneous Disappearance of Diabetic Cataract.—At a recent meeting of the London Ophthalmological Society, Mr Nettleship read a note on the "Spontaneous Disappearance of Diabetic Cataract." So far as his literary researches went he had found that cases of the kind were very rare. Two cases were detailed in Dr. J. Seegen's work on diabetes mellitus. Seegen's first case was that of a man aged thirty-nine, who in July, 1863, about six months after the appearance of diabetes, noticed that his sight began to fail; the lenses were cataractous and hazy. Under treatment at Carlsbad the lenses cleared; the quantity of urine was reduced to one-half, but the percentage of sugar remained the same. In the spring of 1865 the lens again became opaque. The second case was that of a woman aged fifty-five, who was first seen in the autumn of 1867, soon after which the sight began to fail and became misty; she was treated for diabetes in February, 1868, and whilst under treatment the lenses became clear again. Dr. Tannahill's case was that of a coal-miner, who was seen while in prison. He had suffered from diabetes for eleven months; both lenses were opaque throughout, the left more than the right. He was put on the ordinary diabetic diet, and had two grains of opium daily. Whilst under treatment his sight began to improve, the opaque lenses gradually cleared, and on inspection when he was discharged from prison no trace of cataract remained. No satisfactory explanation had yet been offered as to the cause of diabetic cataract. The view that the lens contained sugar was a possible explanation, but the idea of a permanent degeneration was not borne out by the facts just narrated; moreover, there was a reappearance of the cataract in one case. The abstraction of water from the lens owing to an increased density of the blood or fluids surrounding the lens was a likely explanation.

Fracture of the Larynx.—An instance of this rare accident is described by Dr. Berry (*The Lancet*, May 23, 1885). During the afternoon of February 6th, the doctor was called to see G. L.——, aged twenty-one. He was reclining on a sofa, looking very pale. Extending from the tip of the chin to just above the hyoid bone was a superficial wound. The voice was like that of laryngitis. The prominence of the thyroid cartilage was gone. Placing his hand over the throat and requesting the patient to swallow, the Doctor detected unmistakable crepitus of the moving larynx. A more careful examination revealed what felt like a separation of the wings of the thyroid cartilage. The history of the accident was briefly this: About twenty minutes before Dr. Berry saw him he was working a circular-saw, and was suddenly struck in the throat with great force by a large piece of wood coming from below upward. For a few moments he had a hard struggle for breath, but managed to keep from falling by leaning against a bench. Water was brought to him, but he declined it, as he feared it would choke him. With the help of two men he walked home, a distance of about five hundred yards from his work. Having applied a warm-water dressing to the throat, the patient was put to bed, his head and shoulders being raised. An hour later the Doctor saw the patient again in conjunction with Mr. Chaffers, whose help he sought when he saw the case was of such gravity. His diagnosis was confirmed, and seeing the patient was free from urgent symptoms, the breathing being quiet and full and the condition of shock gradually passing off, the physicians considered it best to continue the warm-water dressings and forbid anything being taken by the mouth except ice, leaving word that any change in the breathing should be immediately reported to them. About 1.30 next morning Dr. Berry was called up, as the patient was reported to be choking. After sleeping for about an hour and a half, during which time he breathed rather noisily, he woke up somewhat suddenly and at once began to struggle for breath. When the doctor arrived he was unconscious, the eyes were open and fixed, the pupils dilated, the face pale, and the deep spasmodic efforts to breathe were failing. Having sent for Mr. Chaffers, Dr. Berry at once performed laryngotomy. Still no air seemed to enter, and no mucus escaped from the tube. Having satisfied himself the tube was clear and that no blood was obstructing the air-passages near the wound, he enlarged the opening and replaced the tube, with no better result, death taking place after a few more respiratory efforts had been made. Half an hour after death Mr. Chaffers and himself examined the larynx and trachea as well as they could through the operation wound. Besides the separation of the wings of the thyroid, oblique lines of fracture were made out on each side, through the wings themselves. Within easy reach of the finger, hanging down the trachea by a mere shred of fibrous tissue was a part of the left wing of the thyroid cartilage itself, the size of a finger-nail, apparently the lower front angle; this was easily removed. No autopsy was allowed. During life, there was no spitting of blood, and after death perfectly white frothy mucus welled up from the throat.

Position of the Fetal Head at Term.—As an inaugural thesis in the University of Dorpat, L. Brühl has published some observations on the position of the fetal head and the extent of its entrance into the pelvic cavity at term. In primiparæ the greatest circumference of the head was found to have passed the brim at the end of pregnancy in half the cases. In multiparæ it only reached the pelvic cavity in a fourth of the cases. The reason of the difference is to be found in the greater elasticity of the abdominal wall and of the uterine ligament in primiparæ. In contracted pelves, where the conjugata vera measured less than ten centimetres in primiparæ, the head entered the cavity in only a third of the cases, the greatest circumference in scarcely any passing the brim, and in subsequent pregnancies the position of the head became higher more rapidly than was the case in normal pelves. The prognosis of labor depending upon the relation which exists between the fetal head and the maternal passages, it is the practice in Berne, where these observations were made under the supervision of Professor P. Müller, to grasp the fœtus through the abdominal wall and force the head as far as possible into the pelvic canal at the completion of pregnancy. Generally, when the head has more than half entered the pelvic cavity, one can predict that birth will take place naturally. On the other hand, it is by no means necessary to infer that instrumental interference will be required in all cases where the head has entered the canal to only a slight extent.—*London Lancet*, May 30, 1885.

The Elimination of Arsenic.—The Paris correspondent of the *Lancet* writes that at the last meeting of the Paris Society of Medical Jurisprudence, Professor Brouardel reported a case illustrating the possibility of an infant at the breast being poisoned through its mother's milk. In his capacity of medical jurist he was consulted about a case which was lately brought before the tribunal, in which a man was accused of having attempted to poison his wife with arsenic, which he gave her in her food, she having at the same time a sucking baby. The infant was seized with symptoms of cholerine a few days after the mother had been affected in a similar way—diarrhœa, vomiting, etc., from which it died. These symptoms having occurred during the hot season, no importance was attached to them; but in the month of November following, the wife and mother-in-law of the accused having been again similarly affected, suspicions

were aroused, and Professor Brouardel caused the body of the infant, which had been buried six months, to be exhumed. According to the Professor's report, the body was completely transformed into cadaverous fat, and it was impossible to isolate the viscera from the other parts, so that the body had to be analyzed *en masse*. It weighed about two and a half kilogrammes, and contained five milligrammes of arsenic. Means had been taken to make sure that the arsenic did not come from the linen enveloping the corpse, nor from the earth which surrounded the coffin. The question then suggested itself as to whether the arsenic found in the body of the infant might not have been eliminated by the milk of the mother. To ascertain the possibility of such a circumstance, M. Gabriel Pouchet performed some experiments which were very conclusive. He administered to a certain number of wet-nurses, who were in the St. Louis Hospital affected with skin diseases, from two to twelve drops of Fowler's solution, and he ascertained that in these conditions the milk of the nurses always contained a relatively large quantity of arsenic; thus, the milk of one nurse, who had taken eight milligrammes of arsenic in six days, contained one milligramme of the metalloid to one hundred grammes. M. Pouchet observed that these doses did not affect the nurses or their nurslings in the least. But upon the supposition that the result might be otherwise if a large dose of the arsenic were administered at once, and in order to clear up this point, M. Pouchet tried experiments on some females among the lower animals. This series of experiments did not furnish conclusive results, as animals present a variable degree of susceptibility to arsenic, and it was therefore impossible to draw any comparative conclusions. It may, however, be deduced from these researches that the elimination of arsenic takes place principally through the milk, and it is therefore prudent never to administer arsenic to mothers suckling infants.

Rheumatic Epilepsy.—At a recent meeting of the Société de Médecine de Lyon, M. Teissier called attention to gout and rheumatism as possible factors in the etiology of epilepsy. He related several cases in which persons suffering from these affections had one or more epileptic seizures, and other cases in which epilepsy existed in young persons, members of a rheumatic family. In all these instances the attacks were promptly arrested by bromide of potassium. The author referred to reported instances of epilepsy occurring at the menopause, and suggested that they might also be regarded as of rheumatic origin.—*Journal de Médecine et de Chirurgie Pratiques*, April, 1885.

Terpine and Terpinol.—Terpine is a substance obtained by distillation from turpentine. It exists under the form of clear prismatic crystals, sometimes of large size, soluble in two hundred parts of cold, and in twenty-two of boiling water, and in seven parts of alcohol. Professor Lépine, of Lyons, was the first to use this substance in medicine, and found it to be possessed of expectorant and diuretic properties when given in doses of three to nine grains. In the dose of fifteen grains he found it of value in neuralgia and hystero-epilepsy. Dr. G. Guelpa has, however, made a number of experiments with the drug (*Bulletin Général de Thérapeutique*, April 30, 1885), the results of which were at variance with those obtained by Lépine. He states that terpine exerts no action upon the respiratory tract, nor, in doses under fifteen or thirty grains, has it any effect upon the genito-urinary apparatus. It never caused albuminuria and hæmaturia, as Lépine had asserted, nor was there any appreciable action upon the nervous system. In the stomach it causes a sensation as of a foreign body and gives rise to dyspeptic symptoms. But while these experiments with terpine gave such negative results, a number of trials of another derivative of turpentine, terpinol, were more promising. Terpinol is an oily, colorless liquid, with an odor like that of hyacinths. When taken internally it is eliminated by the lungs, imparting a very strong and persistent odor of hyacinths to the breath, and occasioning a sensation of heat in the larynx and fauces. Dr. Guelpa administered it in doses of about six minims every four hours, in capsules, and found that it exerted a very favorable action in quieting the cough and modifying the secretion in bronchial catarrh. It was well borne even in large doses, the experimenter himself having taken over thirty-five minims in twelve hours without inconvenience. It exerted little or no action upon the genito-urinary tract.

Chloroform as an Hemostatic Agent.—Dr. Spaak recommends chloroform as a styptic in operations, especially about the mouth and throat. He uses it mixed with water in the proportion of one part to one hundred. A case is cited in which a sequestrum, the size of a large nut, was removed from the lower jaw with the loss of hardly a drop of blood. He employs the chloroformed water as a simple lotion or in the form of spray directed to the part, and he much prefers it to the ordinary styptics in common use.—*Journal de Médecine et de Chirurgie Pratiques*, April, 1885.

The Plaster-of-Paris Jacket.—The visit of Professor Sayre to Copenhagen last summer has had the effect of awakening anew, among the Continental surgeons, an interest in the method of treatment of Pott's disease of the spine by suspension and the plaster jacket. In a long paper continued through several numbers of the *Deutsche Medicinische Wochenschrift*, and recently published as a reprint, Dr. H. Nebel treats of the subject very thoroughly. He states that the method had fallen into discredit among German surgeons, and was but seldom employed until after the Congress at Copenhagen. And he attributes its revival in great measure to the exertions of Dr. Phelps, of New York State, who remained for a time in Germany and made a number of applications of the jacket. In Italy, also, the subject has received more attention of late, and in a recent number of the *Archivio di Ortopedia* is published a graduation thesis by Dr. Motta Mario upon "Kyphosis and its Orthopædic Treatment, especially by Sayre's Plaster Bandage." Dr. Mario was a student at the Ospedale Maggiore in Turin, and had the opportunity to observe a number of cases treated in this way. He was well pleased with the results in most of the cases, and hopes to see the method more generally adopted.

Intravenous Injections of Iodine in Infectious Diseases.—Dr. Van der Heyden recommends the treatment of infectious diseases by means of the intravenous injection of iodine. His formula is as follows: Iodine, one part; iodide of sodium, two parts; water, seven parts. The dose of this solution is two and a half drachms for each injection. In a case of typhoid fever an injection was followed by a rapid fall of the temperature, which did not again rise. In cholera he claimed to have obtained good results when the injections were practised early in the disease, but in the algid stage they were barren of results.—*Journal de Médecine de Paris*, May 3, 1885.

Treatment of Otorrhœa.—Dr. Bürkner recommends an ointment of one part of red precipitate to fifteen parts of vaseline in the treatment of furuncles and granulations in the external auditory canal. In the case of profuse and fetid suppuration of the middle ear he employs irrigation with a one per cent. solution of corrosive sublimate, and later an instillation of a one to five hundred solution of sublimate in alcohol. In a number of cases of chronic suppuration of the middle ear treated in this way, a cure was obtained in about one-half. The author insists upon the necessity of caution in the use of this substance in order to prevent its passage through the Eustachian tube into the pharynx.—*Journal de Médecine et de Chirurgie Pratiques*, April, 1885.

The Influence of Intestinal Gases upon Peristalsis.—Professor Arpád Bóckai has been conducting a number of experiments to determine the influence of various gaseous substances upon the intestinal movements. He found that the introduction of hydrogen or nitrogen into the intestine had no effect, while that of oxygen arrested peristalsis previously excited by other means. Carbonic acid, marsh gas (CH_4), and sulphuretted hydrogen caused violent peristaltic movements. These three gases are present in fermentation and decomposition of the intestinal contents, and the author concludes that there is a causal relation between their presence and the diarrhœa which accompanies this condition. — *Deutsche Medicinal Zeitung*, April 30, 1885.

Ischæmic Muscular Paralysis and Contractures.—After a limb has been tightly bandaged for a long time, it is not unusual to find paralysis or contractures of these muscles. This paralysis was stated by Volkmann some years ago to be purely muscular, and to be due to the deficiency in blood-supply caused by the pressure of the bandage. Volkmann's observations, however, passed almost unnoticed. Recently Dr. E. Leser has published a brochure embodying the results of a number of experiments undertaken with a view to test the truth of this theory. He employed rabbits chiefly, and either wrapped the limb in a firm roller or made temporary pressure with an elastic bandage. He found paralysis of the muscles even after the bandage had been on but a few hours. The reactions to the constant and induced currents were weakened or destroyed, although slight contractions could be obtained by applying the current to the nerve-trunks. Normal sensibility was retained. Usually on the following or the second day there was an attack of acute myositis, which gradually subsided, leaving no permanent changes except where movements of the limb were restricted by means of splints. He sees in this the cause of the persistence of the paralysis in men, and he advises strongly against rest and in favor of passive movements in the treatment of such cases. Examination of the affected muscles in two cases showed inflammation with the destruction of a certain number of the muscular fibres.—*Centralblatt für Klinische Medicin*, April 25, 1885.

Removal of a Calculus from the Vermiform Appendix for the Relief of Recurrent Typhlitis.—At a recent meeting of the Clinical Society of London (*Medical Press*, May 13, 1885), Dr. Symonds read the history of a case in which, at the suggestion of the late Dr. Mahomed, he had removed a calculus from the vermiform appendix for the relief of recurrent typhlitis. A basket-maker, aged twenty-three, was admitted to Guy's Hospital July 16, 1883. Six months previously he was seized during the night with pain in the right iliac region; this increased in severity and he became ill generally, and at the end of a week was unconscious, remaining in this state four days. The illness lasted seven weeks. During the first week he vomited everything, and his bowels were not opened for ten days. During the whole time there was great tenderness in the right iliac fossa. During the first part of his illness he was under the care of the parish, and for the last two weeks was in the Camberwell Infirmary, where he was told he had typhlitis. Soon after this, on getting about, he noticed a hard lump in the right groin about the size of a walnut; sometimes this swelling was painless, at other times it was very tender. Since this illness he has had repeated attacks of pain in the right iliac fossa, which come on suddenly, and last one or two days. The pain is relieved by poultices. At first these attacks recurred about once a month, but during the last five weeks he has had six attacks, and they have been increasing in severity. One of the attacks having been observed in the hospital, it was proposed that the cæcal region should be approached by an incision in the right iliac region. Dr. Mahomed was of the opinion that there existed an abscess cavity containing probably a calculus or concretion, and that the periodical occlusion of a communication with the cæcum determined the recurrence of pain. It was finally decided to cut down upon the small hard lump which was to be felt in the right groin on deep palpation. On August 24th chloroform was administered, and under the carbolic spray an incision was made, commencing two inches above and one inch internal to the anterior superior iliac spine, and curving downward and forward for about four inches, being much the same as that used in ligature of the external iliac, and so arranged that its centre corresponded with the position of the lump. The various structures were divided, but the transverse fascia was not distinctly recognized, owing possibly to the incision being rather near the iliac spine. The structures in front were now raised out of the iliac fossa, when the lump could be plainly felt from behind, and as yet the peritoneal cavity had not been opened. A hand pressed duly from the front steadied the swelling, and brought it more into the wound. A vertical incision was now made over the hard lump, and a small calculus exposed. Before removing it a fine silk suture was passed through the tissues just above, so that the orifice might not be lost. The opening was then enlarged, and the calculus removed. The soft and purple mucous membrane of the appendix was seen, and its tortuous course from the aperture could be traced upward toward the cæcum, so that there seemed no doubt of the canal having opened. Exploration of the cavity with a probe failed to detect a channel leading toward the cæcum. No pus or other fluid was found round the calculus, nor was there any fecal or unpleasant odor. The opening into the appendix was closed by Lembert's and the wound by deep silk sutures. The peritoneum was not opened, so far as could be determined, and this was attributed to the adhesions that had probably taken place at the time of the first attack, and to the method adopted in reaching the appendix. The usual gauze dressings were used. The calculus was oval in shape, smooth on the surface, and measured three-fourths of an inch long, and rather more than one-half of an inch wide. On section it showed a laminated calcareous capsule enclosing hardened fecal matter. The patient made a somewhat protracted but complete recovery, and in April, 1885, although an inmate of a lunatic asylum, it was learned that he had never had any bowel trouble since November, 1883. In his remarks on this case, Dr. Symonds points out that this is the first case in which a concretion or calculus has been removed from the appendix vermiformis without, at the same time, the opening of an abscess. He says also that the credit of the procedure must be given to Dr. Mahomed, at whose suggestion the operation was undertaken.

Œdema of the New-born.—In a paper on this subject Dr. Letourneau asserts his belief that the condition is not one related to sclerema. The disease attacks usually premature infants or weakly twins. The little patients are drowsy, refuse to nurse, and cry incessantly. The extremities and face are blue, the pulse is weak or imperceptible. Respiration is scarcely audible, and there is often dulness over the lower portions of the lungs. The temperature is subnormal, falling in one case observed by the author as low as 67.5° F. before death. There is at the same time a rather hard and resisting œdema of the body and extremities. On post-mortem examination the tissues and organs are found filled with venous blood, and a greater or less part of the lungs, usually of the lower lobes, is hepatized. The author concludes that this condition is not an actual disease, but is rather a chronic asphyxia due to incomplete expansion of the lungs. The only treatment which he recommends is the artificial filling of the lungs with air.—*Allgemeine Medicinische Central-Zeitung*, April 25, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 18, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

THE past week has brought no news calculated to reassure those who are anxious for the success of the International Medical Congress and the credit of American medicine. Nearly all the gentlemen appointed on the organization from Boston, Philadelphia, Baltimore, and Washington have withdrawn, while many prominent men in New York (aside from those forced off) and from the West will, we learn, either formally withdraw or informally decline to take any part in the work.

The comments of the medical press are almost uniformly condemnatory of the folly and short-sightedness of the American Medical Association. The *New York Medical Journal*, which was at first a little non-committal, not to say strabismic, in its views, has come out in a forcible denunciation of the American Association, and shows that it is a useless and mischief-making body. The *Louisville Medical News* edits the withdrawal announcements under the head "Destruction." The *Philadelphia Medical Times* suggests that there be a national gathering for the purpose of forming a new organization of the Congress.

The *Journal of the American Medical Association* leads off with a reference to the proverb that things done in haste may be repented of at leisure. The application is meant for Philadelphia, and the writer shows a *naïve* unconsciousness of its immense retro-active pertinence.

At present the best hopes for the future of the Congress lie in the fact that we have two years yet before its meeting. This is time enough for a good deal of hot feeling to subside and for concessions and compromises to be made. There has never yet been a Congress, we believe, without considerable heart-burning. Any hopes in the emollient effect of time, however, need not be cherished unless with them there is seen a prospect of some very radical changes in the personnel of the Executive Committee and the removal entirely of any medico-political issue from the organization and membership of the Congress. A meeting of the American Medical Association, entirely revoking its New Orleans work and restoring the old committee with its liberal policy, might, perhaps, save the Congress. We see at present no other way.

SEXUAL CRIMES AND THE LEISURE-CLASSES.

So far as we have been able to learn, the disclosures made in London by the *Pall Mall Gazette* relate largely to indulgences in sexual crime, and to distinct sexual perversions rather than to ordinary sexual immorality. And it would appear that the most common sexual perversion among British aristocrats is a desire for young and, as they are technically called, "fresh" girls who have reached the legal age of thirteen.

There is one conclusion regarding this matter which medical men are best able to make, and it is one which certainly is often practically brought to their attention. It is that while the sexual passions are most unrestrained among the young, they are most perverted and unrestrained also among those who lead idle and luxurious lives. There never can be a large and wealthy leisure-class without a considerable proportion indulging in great sexual excesses, often of the grossest character. With high living and nothing seriously to occupy the mind, the sexual organs are bound to occupy an excessively large part of the man's thoughts and feelings. The existence of a wealthy and, by virtue of social law, unemployed class, is always a source of social danger, as history shows. The comments of the public press indicate that the exposures of the *Gazette* will give an impulse toward the lessening of the social authority of the British leisure-class. If political economists would devise a way to set them all at work, the traffic in young girls would receive its most serious blow. As it is, we fear that but little of permanent benefit can come from the *Gazette's* revolting disclosures.

THE INTERNATIONAL SANITARY CONFERENCE.

THE International Sanitary Conference, whose sessions at Rome closed last month, is the fifth meeting of the kind that has so far been held. The first Conference was in Paris in 1851, the second in Constantinople in 1866, the third in Vienna in 1874, the fourth in Washington in 1881. None of these meetings has been attended with any very apparent practical results, and for this reason: The membership is composed of diplomatists and scientific men. The latter do all the work and the former go home and recommend that the work be not approved. Such at least has been the general working of the meetings. Commercial and political interests are as yet too strong to allow of the application of rigid sanitary rules to international commerce. One end perhaps has been in a measure gained, and that is the general adoption by sanitarians and by governments of the view that land quarantines and sanitary cordons are useless. And yet even now, if an epidemic breaks out, one or other of these measures is liable to be enforced.

The International Conference at Rome was composed of diplomatic and technical delegates from Germany, Belgium, Spain, France, Russia, Servia, Sweden and Norway, England, Switzerland, Denmark, Turkey, Greece, Austria, India, Italy, Japan, Mexico, Brazil, and several South American States. Among the prominent men of science present were Koch, Moleschott, Brouardel, Proust, Thorne, Fayrer, Semmola, and Sternberg. The discussions were confined to the subject of cholera. So far as we can learn the main results accomplished were the dogmatic reiteration of the opinion that "land quarantines and sanitary cordons are useless;" also the recommendation that ships which have no surgeon be officially inspected by a physician supplied by the consul of the

country to which the vessel is destined. Finally an excellent report was made on disinfectants, a report very similar to that made by the Committee of the American Public Health Association. The United States may credit itself, through its efficient delegate, Dr. Sternberg, with having been largely instrumental in accomplishing what little of practical work was done by the Fifth International Sanitary Conference.

CICATRIZATION IN BLOOD-VESSELS AFTER LIGATURE.

An instructive paper, or rather monograph, was read by Dr. Senn, of Milwaukee, before the last session of the American Surgical Association on the subject of cicatrization in blood-vessels after ligature. A reprint of the paper is now before us. After giving the history of ligature as employed in surgery, and examining the older and most recent views regarding the histology of the blood-vessels, as well as the effects of permanent ligature, the author presents a detailed account of his own investigations and observations. He invariably performed his experiments with strict antiseptic precautions. Fifty-four ligatures were applied in a large number of healthy animals. In twenty-three cases double permanent ligation of arteries was performed, and, in nine, double temporary ligatures were applied. Similar experiments were also made on the veins. Among other things, the deleterious influence of suppuration on the healing process was well shown by the author's experimental inquiries. He found that "in all cases where the wound healed by primary union, the isolated portion of the vessel became adherent, as early as the second day, to the adjacent tissues, and, after a few days more, the interrupted vascular connections were restored."

When temporary ligatures were employed, suppuration, of course, was more frequently seen, on account of the unavoidable interference with reparative processes in the wound. In all cases where suppuration followed operative interference, the vitality of the intervening portion of the vessel suffered. Indeed, if sufficient time was given, this portion of the vessel was, as a rule, found to be completely separated and lying within the abscess cavity. Nevertheless, secondary hemorrhage was never seen as a result of suppuration, nor was sloughing of the intervening portion observed. The author explains this by the presence of a narrow intravascular cicatrix in both ends of the vessel, which "was usually supported by a strong paravascular ring of connective tissue, which formed a part of the thick wall of the abscess." Dr. Senn formulates the following conclusions as to the result of this part of his inquiries :

1. All surgical operations on blood-vessels should be performed under strict antiseptic precautions for the purpose of preventing suppuration.

2. In aseptic wounds the complete isolation of a vessel from its sheath for a distance of one inch is not followed by any serious disturbance of nutrition in the vessel-walls.

3. Suppuration invariably produces a loss of continuity of the vessel at the seat of ligature.

4. Inflammation beyond the limits of the reparative process interferes with the typical formation of the intravascular cicatrix.

Senn's experiments further led him to prefer catgut to silk, horse-hair, or silk-worm gut as suitable for aseptic ligatures. He demonstrated anew the circumstance that properly prepared catgut does not act as a foreign body, and although finally completely absorbed, resists long enough for the occurrence of vascular obliteration. He states that he has never observed a single case in hospital or private practice where the catgut ligature failed to fulfil its purpose of provisional hæmostasis. It never gave way before the definitive cicatrix had become sufficiently firm to resist intra-arterial pressure.

Dr. Senn is also in favor of freely opening the vascular sheath in order to fully expose the vessel to be ligated. He has never seen any harm result from this procedure. Is is to be borne in mind, however, that this teaching is opposed to that of a majority of surgeons, who hold that the vascular sheath should be spared as much as possible.

As regards the time required for permanent obliteration to become established, it was ascertained that it required from four to seven days in arteries, and from three to four days in veins.

There is no doubt that Dr. Senn has conscientiously labored to elucidate a subject, the importance of which requires no emphasis. If his conclusions are in some respects at variance with accepted doctrines, they will all the more stimulate further research. Meantime we may feel quite certain that the double aseptic catgut ligature should be more frequently made use of in our country than is at present done.

AN ENGLISHMAN'S PLEA FOR SPECIALISM.

Dr. Morrell Mackenzie has recently written an article on "Specialism in Medicine" in the *Fortnightly Review*. Himself an admirable type of the new genus medicus, he has naturally used the occasion to put in the best light the justifications and advantages of the modern tendency to a subdivision of the medical art.

Dr. Mackenzie begins by describing, with a candor not entirely devoid of acridity, the feeling against specialists which has existed among English medical men. We infer from his description that this feeling has developed to a far greater extent across the water than here. It has amounted almost to a social ostracism of the class in question. Some of the medical corporations have, we are told, "endeavored to exclude specialists from positions of distinction within their own bodies." The latent feeling has revealed itself "in suggestive shrugs of the shoulders or elevation of the eyebrows at the mention of certain names ; sometimes even in sly innuendo or in mild detraction, which is all the more effective because it is couched in a tone rather of sorrow than of anger. Again, there is the almost indecent eagerness with which any error or oversight on the part of a specialist is proclaimed, and the too obvious intent with which it is made the text of a discourse on the uselessness of specialists. At the dinner-table, at the medical societies, in the gossip that relieves the aridity of scientific discussion, at all places where doctors do most congregate, specialism and its professors were denounced with a wealth of epithet that the refined controversialists of Billingsgate might have envied."

Many of the medical journals catered to this feeling.

Its exponents have even, says our author, intimated that it was not "respectable," and Dr. Mackenzie shows in an amusing way how dearly the average middle-class John Bull hugs to himself this word. In the heart of the medical body corporate the desire to be "respectable" is intensified almost into a passion. Contrasting this condition of things with that in America, he makes the following observation:

"In America, where there is no 'leisured class' to look down upon those who labor, the medical faculty is recruited from the best families in the land, and its members accordingly act with an independence quite unknown in this country. Under these circumstances, specialism, instead of meeting with opposition, was received with open arms. I may say that when I was travelling in the United States three years ago nothing astonished me more than the universal diffusion of specialism. It would be almost impossible to find a city with ten thousand inhabitants in which there were not at least three or four specialists; while in one city, with a population of only one hundred and thirty thousand, I found thirteen specialists exclusively engaged in treating throat diseases.[!] Indeed the practical genius of the American people was never more clearly evinced than in the manner in which it embraced specialism."

Perhaps Dr. Mackenzie exaggerates a little the warmth of the American embrace. Specialism has been taken up enthusiastically by thousands of our young men. It has been received rather frigidly by the elders of the profession, but without any overt opposition. We recognize the necessity for it in our widely scattered population, where there are so many who cannot afford to travel a thousand miles to get the best technical skill.

Dr. Mackenzie calls attention to the fact that the opposition to specialism exists only in the medical profession. There is no obloquy attached to the lawyer who makes probate law, or patent law, or railroad law his specialty; in art, Verboeckhoven is respected though he paints only sheep; Landseer was not thought less of because he painted animals. So with the other arts and sciences, from engineering to philosophy.

But, after all, what is the use of trying to defend or attack specialism when everyone can see that it is an established fact, that it is demanded by the public and is imposed upon the doctor by the extent of medical science and the difficulties of mastering the technicalities of the medical art. No one can deny the utility of the microscope, stethoscope, laryngoscope, ophthalmoscope, and all the other innumerable instruments used in diagnosis and treatment. Yet no one can claim ever to be master of them all. There will come a time, no doubt, when the general consultant, the pure physician, will be eliminated from the face of the earth. Indeed the time is not far away already. The general consultants in this city are after all mainly consulted for their special knowledge of the heart and lungs or abdominal diseases. We are to have, by and by, says Dr. Mackenzie, only the general practitioner, who can never be displaced, and the specialist.

Whether this prospective state of things is to be the best thing for the profession is open to some discussion; but that it will be best for the public must be conceded, for the public demands it.

SELLING LOCATIONS.

As compared with England there is very little selling of practices or locations in this country. For one thing, it is probable that such transfers cannot be made so readily here. A physician's patients believe in him and have a measure of confidence in gentlemen whom he recommends, but they cannot be handed over without question. There is too much competition, and a new man, however recommended, has generally to fight the battle all over again.

It would contribute to the material interests of the doctor, however, if his practice were more of a merchantable article, for it would give him a surer feeling that he had acquired a certain available capital by long years of work. Judging from advertisements in our London medical exchanges, the value of a practice ranges in England all the way from $500 to $6,000.

A correspondent, Dr. G. W. Eddingfield, of Mace, Ind., has written us, urging the need of a more extensive bartering and sale of locations. Dr. Eddingfield argues, on business grounds, that the best thing for a doctor to do, when he finds that some man is crowding him out and drawing off his patients, is to dispose of his practice and seek his fortune elsewhere. We fear that this plan would hardly answer as a rule, for if a physician fails in one place he will probably not succeed in another. The selling of practices must be generally confined to those who find that they are tired of the harness or are in bad health, or infirm from age.

A WISE SOCIETY.

In the midst of the turmoil and strife over the petty issues of political and professional life, it is pleasant to see a medical society grapple firmly and courageously with a momentous question and carry it to a safe and glorious termination. This is what the Vermont State Medical Society did at its last semi-annual meeting in Bellows Falls. Aside from some brief moments devoted to dallying with such trifles as hygiene, purpura hemorrhagica, and antipyretics, the energies of the members were devoted to the elucidation of the following questions: "Shall the Society visit the paper-mill, the machine manufactory, and the brewery?" The first two points were settled immediately in the affirmative. But the question, Shall we visit the brewery? elicited a debate which, for sustained eloquence, logical force, and absence of personal feeling, will ever be memorable in the popular annual volume of Transactions.

The debate was begun by Dr. X, who proved in an easy manner the natural and inherent antagonism which exists between medical men and all forms of alcoholic liquors, and he argued that *a priori* it would be impossible for a doctor to enjoy himself in connection with a decomposing fluid containing at least five per cent. of alcohol. He therefore moved that the invitation be declined. Upon this, however, up rose Dr. Y, and showed that the assumption of the first gentleman was not well grounded. He also instanced, to the intense interest of the Society, the case of a doctor whom he had seen several years before and whom he had known to have drank several glasses of beer with apparent enjoyment.

Then began the storm of rhetorical, technical sesqui

pedalianism to which we have referred, and which, we are credibly informed, made the green hills of Vermont erect themselves several inches higher in pride. Amid this fermentation, the President, having moistened his lips with cold water, and thus preserved his presence of mind, moved to refer the whole matter to the Executive Committee; whereupon this was done and a recess was taken.

The Committee, after having taken copious draughts of milk, consulted the Code, and having found therein nothing bearing upon the subject, finally discovered that a local branch of the Woman's Christian Temperance Union opposed the visit and threatened to "boycott" the Society if it went to what they figuratively called the Sheol of Malted Sin. The ladies offered a compromise, however, viz., that each doctor should take a W. C. T. U. lady in his visit. The Committee made their report, and, having wisely or otherwise exhibited certain photographs of the temperance ladies, after another stormy discussion it was unanimously voted to accept the invitation, but to go alone.

The good ship of medical state thus safely weathered the breakers of disaster, and went through the brewery without touching a drop of its poisonous product, except sufficient to destroy the effects of a change of water.

THE MORBILITY AND MORTALITY OF MEASLES.

A NUMBER of statistical investigations which have been recently made appear to show that measles[1] is increasing in some parts of the world, while in many places it does not decline in the same ratio with other zymotic diseases. Thus in Paris the mortality from 1869 to 1874 was 3.03 per 10,000 inhabitants; from 1875 to 1879 it was 3.73; and in 1880, 1883, and 1884, it gradually rose to 8.55 per 10,000. In New York City the mortality from measles was, in 1874, 319 among 30,709 deaths; in 1883 the number was 716 to 34,011 deaths; and in 1884, 762 in 35,044 deaths.

Whether increasing or not, it is evident that measles is a source of mortality which is by no means insignificant. According to the last census the total number of deaths from measles in 1880, in this country, was 8,772 in a total mortality of 756,893. This makes the mortality at about the rate of 1.7 per 10,000 inhabitants. In certain parts of France, including Paris and many large rural districts, the mortality is much higher than this, and in some of the smaller cities it has reached 24 per 10,000 (Sainte-Menehould), and even 40 per 10,000 (Epernay).

In the United States a curious disproportion exists between the South and North as regards the mortality from measles. In nearly every Northern and Western State the deaths from scarlatina are twice as numerous as those from measles, while in most Southern States the reverse is the case. Thus, in ten Southern States and one Territory the total annual mortality from measles was 2,113, that from scarlatina 1,838. This gives a ratio of 2.6 deaths per 10,000 inhabitants from the latter disease, while the ratio in New York State was 1.6 per 10,000.

There seems to be a greater proportional amount of fatal measles, therefore, in the South, and the disease in that section is more serious to life than scarlet fever. It is just possible that this excessive mortality is an accidental one, due to causes prevailing during the census year. Also that an indirect mortality from the sequelæ of measles occurs in the North sufficient to equalize the ratios. We regard such an explanation, however, as improbable.

It is known that there are certain countries where measles is always a serious disease. It does not appear to be the climate which produces this mortality, since it is in such regions as Finland and the Baltic coast, Brazil and the borders of the La Platte, that it is excessive.

It is generally stated that measles is more fatal in adults. However this may be, and we consider the fact not well proved, it is certain that, among infants and children, the mortality-rate is in inverse ratio to the age. In New York City the measles is most fatal in the second year of life, during which time one-third of all the deaths occur ("Annual Report New York City Board of Health," 1874, pp. 346, 347); next comes the first year of life, then the third and fourth. After the fourth year the mortality from measles is very small, while from the tenth to the seventieth year the total mortality amounts to only about three per cent. of the total. The statistics of Eloy, for Paris and Rheims (*L'Union Médicale*, 1885, p. 767), and those of Hecquet, for Abbeville ("Mém. de l'Acad. de Méd.," 1867, t. xxi., p. 529), show that the mortality also rapidly falls after the eighth year.

The records of the Health Office in this city, the statistics of Fox, and those of Eloy for Paris, show that a very large measles mortality occurs in the first year of life. In Paris it has even exceeded that for the second year.

The practical conclusions, from a study of measles mortality and morbility are that it is a disease which kills, if at all, in the first five years of life, before the school age, and that the efforts of preventive medicine should be directed toward keeping it from attacking this period of life. Elaborate regulations connected with schools are all very well, but they do not strike at the root of the matter. Not half a dozen school-children in New York City died of the measles in 1874.

[1] The learned authors of Diseases of Children, Drs. Meigs and Pepper, write an excellent chapter on measles, in which they use the word as a plural. This use of the word is seen too frequently. Though based on dictionary authority, it is palpably incorrect. "Spots" may be a plural noun, but "the spots" is a noun in the singular number.

SOME COMPARATIVE STATISTICS OF THE TREATMENT OF DIPHTHERIA.

CONTRIBUTIONS to the therapeutics of diphtheria are very numerous and for the most part very valueless. What the medical profession want just now is to know what measures will not help diphtheria rather than what will. Some such contribution as this has been made by Dr. N. Lunin, of St. Petersburg, who has presented (*St. Petersburg. Med. Wochensch.*, Nos. 6 u. 7, 1885) the results of a study of 296 cases of diphtheria treated in the Children's Hospital of the Princess of Oldenburg.

Dr. Lunin classifies his cases with reference to treatment into the fibrinous and the phlegmonous-septic forms. He also divides his cases into the naso-pharyngeal and the laryngeal and tracheal varieties. The first two classes, which included the larger number, were submitted

to treatment by corrosive sublimate, tincture of iron, chinolin, resorcin, bromine, and oil of turpentine.

Fifty-seven cases were treated with corrosive sublimate. The throat was pencilled every two hours with a one per cent. solution, and was washed with a solution of 1 to 5,000. Wine and musk were also given.

Ninety-four cases were treated with tincture of chloride of iron, of which from one to eight cubic centimetres were given daily—an insufficient amount no doubt in many cases. The throat was gargled every two hours with a solution of boracic acid and stimulants administered.

Chinolinum purum, recommended by O. Seifert, was tried in twenty-eight cases. The throat was frequently pencilled with a five per cent. solution and was gargled or irrigated with a 1 per 1,000 solution.

Resorcin was given in 27 cases, upon the recommendation of Andeer. The throat here was pencilled with a ten per cent. solution and irrigated with a one per cent. solution.

Bromine was used in 33 cases, according to the method recommended by Hiller. The bromine in one-fourth to one-half per cent. solution, with bromide of potassium, was pencilled on the throat every three or four hours, while the bromine in solution (.6 to 1.00 per 300) was inhaled from every half hour to every two hours.

Oil of turpentine was given in 23 cases, according to the methods of Bosse and Satlow. The oil was given internally in doses which were gradually increased up to ten drops hourly or two hundred and forty drops per day. This large amount caused no disturbance of the stomach. The throat was gargled with a boracic-acid solution, and wine and musk administered as in all the cases.

The results of these various treatments are best shown in the following table:

Method of Treatment.	Fibrinous form.			Phlegmonous septic form.			Total.		
	No. treated.	No. of deaths.	Per cent.	No. treated.	No. of deaths.	Per cent.	No. treated.	No. of deaths.	Per cent.
Sublimate	43	13	30.2	14	13	92.9	57	26	45.6
Iron	43	14	32.6	51	39	76.5	94	53	56.3
Chinolin	19	6	31.6	9	9	100.0	28	15	53.0
Resorcin	10	2	20.0	19	17	89.5	29	19	65.5
Bromine	15	7	46.7	18	16	88.9	33	23	69.7
Turpentine	12	1	8.3	11	9	81.8	32	10	43.4
Total	142	43	30.3	122	103	84.4	264	146	55.3

It will at once strike the reader that the results of treatment by any of the above methods are not very encouraging. Neither can we lay the blame on the constitution and condition of the child; for Dr. Lunin asserts that of 296 patients, only 25 were badly nourished, while 225 were well developed and well nourished.

According to the table we must infer that in the phlegmonous-septic form iron is the best remedy, as the mortality-rate under it was 76.5 per cent. On the other hand, in the fibrinous form oil of turpentine stands at the head. Bromine does not take a high rank in either form. Chinolin and resorcin were also disappointing.

THE QUESTION OF THE FAILURE OF MEDICAL CIVIL SERVICE REGULATIONS.

We took occasion just after the first civil service examination for medical positions under the city government to offer some mild criticisms as to the manner of conducting such a test, particularly with reference to the selection of the fittest man for office. In this editorial, while commending the scheme of medical civil service examination as admirable, we expressed the fear that such examinations might be so conducted as to enable merely "crammed" men to have an undue advantage over more practical men who had not recently enjoyed the advantage of that mental gorging known as a "cram quiz." We also offered some suggestions as to the future management of examinations, by while more practical tests might be applied. Finally, after expressing our hope and confidence that a perfectly fair system of selection would eventually be elaborated, we pointed out that the weak point of the present system was that the best men, according to the tests employed, were not necessarily chosen for office, but could be passed over to make place for men standing lower in the scale having political influence.

It seems the logic of events has confirmed these fears, and accordingly in our last issue we expressed ourselves as again disappointed with the present practical working of our municipal civil service system, inasmuch as the men standing the lowest in two medical examinations were appointed to office as quickly as those standing high on the list, while many of the latter, who were without political influence, have been completely ignored. In the first of these examinations, a man standing among the lowest in grade was one of the first to receive a position in the Health Department; and, as stated in our editorial of last week, in the second list, the man ranking first was passed over, while the man holding the seventy-sixth place was chosen, simply because he had a stronger political backing.

In view of these *facts*, it is with a mixture of surprise and amusement that we notice two editorials in the *Evening Post*, calling The Medical Record to task for some "loose writing" about the working of the municipal civil service rules. We would hasten to call the attention of our contemporary to the fact that when we stated in our first editorial that it was "possible for anyone standing quite low on the list, but having strong political influence, to obtain an office," we were *not* guilty of a "gross blunder," and we most excusably repeated the statement.

The *Post* states that the appointing officer is obliged by the rules to fill a vacancy from the first three names on the list, if any of the owners will take the place. We can fancy the smile that comes over the countenance of not a few who passed high in the late examinations, but who have not been anxiously pressed to take any place—in fact, have heard nothing more from the appointing powers, while the offices have been quickly filled by men taking a much lower percentage in the examinations. It is with some diffidence that we assure our learned, but mistaken contemporary that the best that can be said at present of our municipal civil service system is that it is purely negative, inasmuch as a man must pass some test before being considered eligible to office, but after that the lowest as well as the highest go into office usually in direct ratio to the influence employed.

Hospital Stewards.—A general order has been recently published limiting hereafter to the enlisted men of the army all appointments as hospital stewards.

News of the Week.

Virginia State Board of Medical Examiners.—Some practitioners in Virginia, says the *Virginia Medical Monthly*, are rebelling against the State law which requires that they shall first secure certificates from the State Board of Medical Examiners before undertaking practice in Virginia. One or two court clerks, indeed, have even refused to recognize the law. All such parties are forewarned "that they are violating the law, and that after a due amount of tolerance has been exhausted, they will be arrested and made to test the constitutionality of the Act of the General Assembly." Twenty-eight States and Territories now have State or Territorial Examining Boards, and it will not be long before all the other States will have like protections against impostors and incompetent pretenders.

Philadelphia Medico-chirurgical College.—Dr. Le Sieur Weir has resigned the Chair of Dermatology.

The New York Post-graduate School and Hospital has received a donation of $1,000 for a children's ward, and $1,000 for the general hospital fund.

St. Luke's Hospital has recently received a bequest of $7,000.

The Missouri State Board of Health held a stated meeting in St. Louis, on July 3d, perfected its organization, and transacted official business. The Board consists of three physicians, one eclectic, one homœopath, and two farmers and stockmen. Although the Legislature at the last session failed to provide for the continued financial support of this body, the Governor and other State officials say they are earnestly desirous of its continuance, and have pledged themselves to use their influence with the next Assembly to provide for the deficiencies created by the failure of appropriation by the last one.

Professor Leube, of Erlangen, succeeds Gerhardt in the Chair of Medicine at Wurzburg.

Professor Billroth has received from the King of Portugal a very much prized and rarely bestowed decoration, viz., the gold collar and star of the Order of St. Jacob. This is bestowed for surgical services rendered at his Majesty's court.

An Æsthetic Surgeon.—Mr. Lawson Tait will not have homely women as nurses.

Further Withdrawals from the Organization of the International Medical Congress.—All the members of the organization of the International Medical Congress, appointed from Boston, twenty in number, have, as we intimated in our last issue, withdrawn. The Baltimore members, twelve in number, have also withdrawn. The same action has been taken by the Washington members. We hear also of resignations coming in from St. Louis and other Western cities.

The Fate of Successful Patent Medicine Men is not always happy. Ayre and Helmbold became insane, and now we hear that Perry Davis, of "Pain-Killer" fame, is a lunatic in a Philadelphia almshouse.

Fighting the Patent Medicine Trade.—A mixed commission of twenty-four persons, made up of physicians and pharmacists, has been constituted at Berlin, with the object of taking steps to prevent the further extension of the patent medicine trade in that city. At the first meeting a resolution was moved to petition the chief board of police in Berlin (Konigliches Polizei Præsiduum) to follow the example set by corresponding boards in Frankfort-on-the-Main and Carlsruhe, in publishing from time to time in the daily papers popular instructive articles on the subject of patent medicines.

M. Ferrán's Opinion of Christ and Pasteur.—M. Ferran's intellectual balance is pretty well shown by the following, which is credited to him by the *Journal de Médecine*: "The two greatest men that humanity has possessed are Christ, who has given us moral redemption, and Pasteur, who has given us the laws which can lead us to our physical redemption."

The Death of Dr. Rufus H. Gilbert, of this city, occurred last week. Dr. Gilbert achieved fame as an engineer and railroad man rather than as a physician. He was the originator of the elevated railroad system of this city, and for a long time the Sixth Avenue Road went by his name. Dr. Gilbert was born about fifty-five years ago in Guilford, Chenango County, this State. He studied medicine with Dr. Willard Parker in this city, and was graduated from the College of Physicians and Surgeons. He returned to Corning and built up a large practice there. At the breaking out of the war he joined the Duryee Zouaves as a surgeon, and went through the rebellion, performing at the battle of Big Bethel the first surgical operation under fire made during the war. He rose in the service, and was finally made Medical Director and Superintendent of the United States Army Hospitals, having under him many of the most distinguished surgeons in the service. Upon the close of the war his health prevented his pursuing his profession, and he entered the railroad business.

The Wife of Dr. Frank H. Hamilton, who died on the 4th inst., was of such an unobtrusive disposition that few, even of her most intimate associates, have ever known to what an extent she has aided her husband in his literary and scientific labors. Without special technical training, she yet kept herself familiar not only with her husband's famous cases, but with the literature of the profession, and was his constant adviser and confidant in the preparation of his volumes, as well as his most valuable aid in the work of proof-reading and revising. Not a page of any one of the seven revised editions of his work on "Fractures and Dislocations" (a book of one thousand octavo pages), but had the benefit of her suggestions in the manuscript and her trained eye in the correction of technical, as well as typographical errors; and the same may be said of his "Treatise on Surgery," and "Military Surgery and Hygiene."

Disinfection of Rags.—We learn that the Committee on Disinfectants of the International Sanitary Conference unanimously recommended that rags should not be treated as ordinary merchandise, and that as a matter of prudence, and in consideration of the great interest at stake, disinfection of rags was to be recommended.

Consulting with Homœopaths.—The wife of Mr. Bayard, Secretary of State, has been lying ill at Wilmington, Del., under the care of a homœopathic physician, Dr. Negendank. The daily papers assert that regular physicians, among them Dr. Gardner (Garnett?), of Washington, have been in consultation with the physician in attendance.

The Cholera.—There does not seem to be any material difference in the progress of cholera in Spain. It is slowly extending, and, if we may credit reports, it is attacking over a thousand persons daily. The number of victims has, therefore, already far exceeded thirty thousand. The reports about Ferrán's inoculations continue to be indefinite; but, on the whole, confidence in his methods is waning. Cholera is said to have reappeared in the South of France, but information on this point is hard to get.

Men as Trained Nurses.—An association has been formed in London for the purpose of training men as nurses. The promoters believe that many men would rather be attended in illness by their own sex than by women. Bachelors, and widowers residing in chambers, and some men in families would, it is thought, employ properly trained men.

An Honor to Dr. Brown-Séquard.—The great biennial prize of twenty thousand francs has been awarded by the Academy of Sciences to Professor Brown-Séquard. His principal competitor was the celebrated African traveller, M. Savorgnan de Brazza. The biennial prize is awarded in turn by each of the five Academies which form the Institute; it is, therefore, in reality a decennial prize so far as each Academy is concerned. While the reward, which thus crowns the life and labors of a most eminent man, is hailed with universal applause, it is a matter of regret, says the *Medical Times and Gazette*, that Professor Brown-Séquard should not be a member of the Academy of Sciences or of the Academy of Medicine. In other countries these scientific distinctions would have been conferred upon him long ago by acclamation. In France the system of "close boroughs," which prevails throughout the scientific organizations, seems to result in the exclusion of many an eminent man, who has excited the jealousy or dissatisfaction of certain members of the scientific aristocracy. Many a man of second-rate capacities enters the hallowed precincts, because his very moderate capacities have never given offence, while candidates of the highest rank are neglected.

How to Remove a Plaster Bandage.—Dr. G. Krosz writes that the removal of a plaster-of-Paris dressing is greatly facilitated by first scraping a groove with a knife, and then dropping along it a solution of caustic soda. In a few minutes the plaster becomes pulpy along this line, and the bandage can then easily be cut through. If two lateral grooves be made, instead of one, a lid can be cut out of the bandage, the leg can be lifted up for the necessary inspection and returned, the lid being reapplied and retained with a roller bandage. In this way the plaster dressing is not cracked, and the limb is not jolted in the efforts to remove the bandage. By this method, also, it is a very easy matter to cut any fenestra that may be needed.—*Deutsche Medicinal-Zeitung.*

Reviews and Notices.

A Treatise on Practical Chemistry and Qualitative Organic Analysis. By Frank Clowes, D.Sc., London, Professor of Chemistry at the University College, Nottingham, etc. 12mo, pp. 376. Philadelphia: Lea Brothers & Co. 1885.

This work is especially adapted for use in the laboratories of schools and colleges, and the present volume is the third American from the fourth English edition. The author is to be congratulated on the valuable treatise he has prepared. The style is clear, the language terse and vigorous. Beginning with a list of apparatus necessary for chemical work, he gradually unfolds the subject from its simpler to its more complex divisions. The analytical methods, he states, have been thoroughly proved by himself and by his students. It is the most readable book of its kind we have yet seen. There is a certain fascination about it which must certainly communicate its spirit to the labors of the student. It is, without doubt, "a systematic, intelligible, and fully equipped laboratory guide and text-book."

The Ten Laws of Health; or, How Diseases are Produced and Prevented. By J. R. Black, M.D. 12mo, pp. 413. Philadelphia: J. B. Lippincott & Co. 1885.

We cannot too highly commend this household guide to right living, with all its attendant blessings. It might well be styled The Modern Decalogue, so pregnant are its suggestions with good to physical humanity. The ten laws here presented are in turn those relating to pure air, proper food and drink, exercise, suitable clothing, sexual hygiene, climate, occupation, personal cleanliness, rest and sleep with proper mental tranquillity, and intermarriage of near blood-relations. These topics are discussed in order, in relation to their full bearing on the health of the family and the preservation of the home from the inroads of disease. The penalties for violating these laws are forcibly dwelt upon, not in the words of a mere alarmist, but from the standpoint of one whose facts are drawn from personal experience, and who most thoroughly believes in "preventive medicine."

Part II. discusses the germ theory of disease and is put into popular language. The key-note of its teachings lies in these words: "The *only time* and the *only place* for effectually stamping out a pestilential infection in any city, town, or hamlet, is at the *bedside of the very first cases* of the disease." Surely no doctrine could be sounder. The methods of contagion from the common infectious diseases—diphtheria, scarlatina, typhoid, etc.—are plainly given and followed by minute directions for disinfection. That the book has found a place in the minds of the public is attested by the fact that the present is the third edition.

On Some Common Injuries to Limbs: Their Treatment and After-treatment, including Bone-setting (so-called). By Edward Cotterel, M.R.C.S., Eng., L.R.C.P., Lond., late House Surgeon University College Hospital; Atkinson Morley Surgical Scholar, University College, London, etc. With illustrations. Imp. 16mo, pp. 108. London: H. K. Lewis. 1885.

The aim of the little work is to call attention to the necessity of paying due attention to slight surgical affections, especially sprains and injuries to the joints. The importance of rightly managing these surgical "slight ailments" can hardly be over-estimated. It is success or failure in these cases that makes or mars the young practitioner, and the knowledge imparted in this handy little volume is precisely that which may save him from disaster on the threshhold of his career. Even older surgeons will find the hour spent in reading these pages by no means wasted.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 13, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. E. G. JANEWAY presented, in behalf of a candidate, a specimen of *dissecting aneurism of the aorta.*

DR. A. G. GERSTER presented four specimens of

ADENOID CANCER OF THE RECTUM,

all removed by operation. Clinically and pathologically surgeons distinguished between epithelioma and adenoid carcinoma of the rectal mucous membrane. The former was less malignant, of slow growth, and of not a very marked tendency to local and systemic dissemination. It rarely penetrated the perirectal tissues, hence a complete removal was more easily accomplished than in cases of succulent adenoid carcinoma. These have a pronounced tendency to rapid growth, with infiltration, early ulceration, and frequent hemorrhages.

It is to be regretted that a great proportion of these formidable growths remain undetected until their extent precludes a safe and complete removal.

As to their causation, it is of some interest to note that all of the four patients had been suffering from hemorrhoids for many years and were accustomed to the regular use of enemata. The seat of the disease in these four cases was the left side of the rectum; that is a place where the point of the syringe, introduced by the right hand, would naturally and did impinge upon the mucous membrane. Aside from these, Dr. Gerster had taken pains in other cases of rectal trouble to ascertain similar data, and had found that the habitual use of enemata is a very probable source of many forms of rectal disease.

As regards the therapy, doubts as to the propriety of the exsection of the rectum still prevail. But in cases where the possibility of a complete removal offers fair chances, the indication to remove the deadly growth stands paramount. Among palliative measures scraping out of the cancerous masses deserves the first place. If the growth be somewhat distant from the anal margin, a posterior incision through all the soft tissues will prepare a way to the growth, and will afford natural means of drainage.

Colotomy is a very extreme measure of doubtful value, and should be reserved for the most hopeless cases, that are bedridden, or where the tumor is entirely inaccessible. The patient's condition after colotomy is truly pitiable, and it is not a wonder that most of them rather choose the more dangerous operation of exsection.

With the improved technique of operative procedures, this operation also has become safer. The principle of securing each and every mass of tissue by double ligature, and dividing between these, will diminish hemorrhage, the most formidable danger in exsection of the rectum, to a minimum of a few ounces. By occluding the distal end of the gut by clamp or ligature, the escape of rectal contents and injection of the wound will be guarded against during the course of the operation. The first part of the dissection, until the pelvic fascia is exposed and severed, is not laborious, especially in male subjects or in women with a narrow pelvis. After the division of the fascia the organ readily yields to traction and can be well exposed, but the possibility of opening the peritoneum is imminent, or frequently unavoidable. Yet, if injection from without can be excluded, this would nowise increase the dangers. The chief danger is injection from without, and all endeavors have to be concentrated on escaping it. One of the four patients lost his life through retroperitoneal phlegmon due to a fault in the technique employed, which well deserves some mention. If after ablation of the gut the stump is left too short—that is, for fear of injuring the peritoneum, not enough of the intestine is dissected out—the stitches fixing it to the cutaneous margin will prematurely cut through, and will permit its retraction into the bottom of the cavity. And as it is a well-known fact that even the most careful preparative treatment does not always succeed in clearing the thick gut of elderly patients of all fæces, it will happen that intestinal contents will escape through the retracted stump, will soil the fresh wound, causing a septic form of suppuration, which will rapidly extend up the front of the sacrum. If an infection take place during the first three or four days after the operation, especially when the peritoneal cavity had been invaded, the patient will generally succumb.

CASE I.—E. T——, porter, aged twenty-seven, had rectal trouble since his eighth year; general condition good. Adeno-carcinoma of left and posterior side of rectum, situated about one inch and a half above sphincter ani. Tip of index-finger can just touch healthy mucous membrane above the tumor. Exsection of rectum at Mount Sinai Hospital, November 18, 1885, preceding exsection of coccyx under ether. Peritoneum exposed, not injured. Long intestinal stump attached to skin by four stitches. Large wound packed loosely with iodoformed gauze. During operation frequent irrigation of the wound with corrosive sublimate one to five thousand. Loss of blood very small. No shock, although the operation lasted two and a half hours. Exsected piece of gut five inches long, the elliptic growth two by three inches in diameter. Temperatures slightly elevated; general condition good under small doses of morphine up to November 21st, when temperature rose to 103° F., but in a few weeks fell to the normal figure. This elevation was due to indigestion. Bowels moved by castor-oil on November 24th. From this date on daily sitz-bath and uninterrupted cure.

In this case the sphincter ani had been preserved, and to restore its function a plastic operation was performed February 28, 1884. The patient was presented at the New York Polyclinic May 12th, exhibiting good retentive power.

CASE II.—H. M——, tailor, aged fifty-three; small thickset man. Adeno-cancer of rectum, occupying almost its entire circumference, with its centre on the left side, ulcerated, firmly attached to prostate. Its upper edge can be barely reached by the tip of the index-finger. General condition good.

Operation under ether January 14, 1885, at Mount Sinai Hospital. Very difficult and tedious dissection on account of the narrow and deep pelvis, and the close adhesion to the prostate. A rather short stump was stitched to the skin. Dressed as Case I. Length of gut removed five and a half inches. Up to January 19th everything went well; then fever set in, and the dressings being removed it was found that the stitches had cut through, the stump was retracted, and the wound extensively soiled by fæces. Thorough disinfection could not be attained, and patient died of septicæmia January 23d. Post-mortem examination revealed a number of retroperitoneal abscesses. In one corner of the wound a brittle fragment of sponge was found imbedded in the granulations.

CASE III.—Mrs. E. H——, aged fifty-three, flabby, fat woman, with large frame and a poor circulation. Semi-spherical soft adeno-carcinoma occupying posterior and left side of rectum. Healthy mucous membrane beyond the tumor easily palpable. Exsection of coccyx and removal of four inches of gut, together with the sphincter, on February 6, 1885, at the German Hospital. Easy operation, slight hemorrhage. February 11th, temperature rises to 102° F. Dressings were removed, and a portion of the wound was found coated. Diarrhœa attributed to the use of corrosive sublimate had set in, wherefor hourly irrigations with vin. camphoratum were ordered, together with opium internally. By February 16th her appetite had become quite keen; the wound was clean and granulating. By February 21st it had much diminished in size. March 5th set in with dyspnœa,

cough, and slight icterus, with somnolency. Next day the temperature rose to 103° F., and rusty sputa appeared. Repeated careful examination of the wound, and especially of the retroperitoneal region, by inserting a long aspirating needle revealed no local disturbance. Patient died March 14th. Autopsy confirmed the diagnosis of hypostatic pneumonia. Abdominal organs were found normal. Long-continued recumbent posture of the flabby patient, with a weak heart's action, was the cause of the fatal pneumonia.

Case IV.—C. F——, drayman, aged sixty-eight. Extensive ulcerated adeno-carcinoma of terminal three inches of rectum, a portion of it on the left side projecting externally in the shape of a sessile tumor. Koprostasis, pain, and hemorrhages have undermined the patient's health to such an extent that an exsection is out of the question. On May 7th, ether being administered, such portions of the growth as would yield to a sharp spoon were thoroughly curetted out, and the external growth was removed at the same time. To prevent secondary hemorrhage and yet to permit the escape of gases a tampon canula was inserted into the lower portion of the gut. It consisted of a short piece of stout rubber gas tubing, wound about with iodoformed gauze. No reaction followed, and the patient felt quite comfortable, especially after a thorough evacuation of the thick gut had been attained by administering a purge. The tampon tube will cause tenesmus, unless the sphincter ani was first put out of action by the disease or by section or stretching.

The President said that the text-books spoke of the disease as occurring more frequently in women than in men, but according to his experience it occurred most frequently among males.

Dr. Gerster said he had observed twenty-one cases, and in those the sexes were nearly equally divided.

Dr. Boldt referred to the use of peptonized-milk for two or three weeks prior to operations similar to those performed by Dr. Gerster, and for the purpose of avoiding the formation of scybalous masses.

Dr. Gerster said the method adopted in his cases was for a week or ten days to restrict the patient to a strictly liquid diet, to administer once or twice an active purgative, and at the same time give twice a day a large injection; but despite this method, in the cases reported, large masses of fecal matter came away in a comparatively short time after the operation.

Dr. L. H. Sayre presented a specimen with the following history:

POTT'S DISEASE: SPONDYLITIS COMPLICATED WITH MYELITIS.

February 10, 1882, M. L. E——, thirty-one years of age, was brought to me by Dr. Janeway, for the purpose of applying a plaster jacket.

History.—On February 27, 1881, while driving in a very dark night, he was thrown from his wagon over the dash-board, turning almost a complete somersault and wrenching his back very badly. He was exposed in a cold rain for nearly five hours before he reached home, having to drive six miles; was in his wet clothes for some time after arriving home. Commenced complaining of severe pain in his back from that time; applied various liniments and plasters for three months without any benefit. Then consulted Dr. C. F. Gaylor, who advised him to take exercise. This increased his pain to such a degree that he was compelled to keep quiet, resting most of the time on a sofa or lying down on the bed. He then applied to Dr. Janeway, who applied hot irons to his back in five places. After some weeks, Dr. Janeway observed a slight knuckle or projection in his spine, and advised him to come to me.

Present condition.—Has numbness in both feet; right one the worst, feeling as if it was asleep; cannot walk down stairs or step over the gutter without assistance; cannot stoop to pick anything from the floor without squatting; the least movement of the spine hurts him; jarring on his heels hurts him very badly; pressure on his head or shoulders greatly aggravates his pain. Partial suspension by the armpits and head gives him great relief. There is very slight prominence of the eleventh and twelfth dorsal spines, which become less prominent when suspended, and, when he became properly suspended, the pain was entirely relieved.

Diagnosis.—Spondylitis of the eleventh and twelfth dorsal vertebræ and probably the first lumbar, with myelitis.

Treatment.—Rest in the horizontal posture, with ice to the spine; cups, first dry and then wet; afterward, suspension and the application of a plaster-of-Paris jacket.

On March 9, 1882, a plaster jacket was applied without the jury-mast; but this failed to entirely relieve the pain, and on March 18th the jury-mast was added, which gave him perfect relief from pain.

On April 10th the jury-mast was removed, as he said it was so conspicuous; a modification of the jury-mast was then applied.

On May 28th a new jacket was applied, the same head-support being adjusted, although he admitted it was not so effective as the original jury-mast; and in the following August it was taken out entirely, as it did him no good. Two months later a new jacket was applied and the jury-mast left out entirely.

One month after this, however, he requested that a new jacket be applied with the original jury-mast as in the first, as the modified jury-mast caused him great pain whenever he was subjected to any jar. This was not the case with the jury-mast; he was then perfectly free from all pain.

By November 11, 1883, he was so much improved that the plaster jacket was applied as a corset without the jury-mast, although he at that time was unable to move his legs naturally; with the new jacket on, however, he was free from pain in the spine. This jacket was applied at his own house in South Yonkers.

On April 22, 1884, he was able to come to the office and have a new corset applied; but he looked badly, and stated that he had been examined for some throat troubles, and I was afterward informed he had tubercular laryngitis, and from another source I heard he had malignant disease of the throat. A sister of his had died previously of tubercular laryngitis.

During this time he had been able to come down and attend partially to business in New York as long as his jacket remained good.

He had sued the city for damages, carrying it from one court to another and attending the trials, and had been greatly bothered by his creditors; so that this mental anxiety and worry, combined with the disease of the spine and throat difficulty, tended to run down the man, whose strength was already almost overtaxed by his bodily ailments.

During this trial several of our eminent men testified for the defence their belief that the disease was not that of spondylitis or true disease of the vertebræ, but rather that the cord alone was affected. My father, Dr. L. A. Sayre, appeared on the witness stand and endeavored to demonstrate to the Court the effects of the plaster jacket and jury-mast in this case, and in all diseases of the spine, and the painful effects of its removal while disease of the spine was so existing.

The result of the trial finally was a verdict for the plaintiff.

In March, 1885, the wife of the patient came to me and requested me to put a new jacket on the man at the house, as he was unable to come down. I had only seen him once or twice during the past year, and thought he was doing well or I should have heard from him. Being unable to take charge of the case at his own house, I referred him to Dr. Robert Taylor, who had frequently attended him with me. This she accordingly did, and I

heard nothing more until a few weeks ago, when I heard he was very ill indeed, but was under the care of Dr. Moffatt, of Yonkers, from whom I secured the following information.

For some two weeks prior to his death he had complained very much of his back and legs, gradually becoming weaker, with sharp pains in the head, passing from the base of the brain up to the forehead. Two days before his death paralysis of the right side occurred, extending from the toes to the head, the facial muscles being also involved; a slight improvement occurred in this respect during the following twenty-four hours; he then passed into a comatose condition, remaining so up to a short time before death, when he seemed to regain consciousness for a few moments, and his wife states moved the arm and leg of the previously paralyzed side. He, however, again relapsed into unconsciousness, in which condition he remained until death.

During this last sickness the patient was under the care of Dr. H. Moffatt, of Yonkers, who diagnosticated the case as one of tubercular meningitis, and treated him accordingly.

Autopsy on Martin L. E——, by Drs. E. Develin, H. Moffatt, and Biggs, May 6, 1885, thirty-eight hours after death. Rigor mortis well marked; body emaciated. Enlargement and partial consolidation of spinous processes of twelfth dorsal, first, second, and third lumbar vertebræ. Spinal canal opened and cord removed. In the body of the second lumbar vertebræ was an abscess cavity of the size of a large hickory nut; the intervertebral disk between the first and second lumbar vertebræ was absorbed, and the cavity of the latter communicated with that in the body of the vertebræ. The cartilage between the third and fourth lumbar vertebræ is also absorbed. From this cavity and the abscess cavity of the second lumbar vertebræ communications existed into a large psoas abscess which passed down to a point just below Poupart's ligament on the right side, but had not pointed externally; this contained about a pint of fairly healthy-looking pus with clots of broken down tissue. There was also an opening from the fourth and fifth lumbar vertebræ where the cartilage was absorbed, extending into the spinal canal itself, from which pus was seen flowing. The cord was removed for microscopical examination. Brain: Tubercles were found along the fissure of Sylvius, crura, and medulla; no effusion into the ventricles; very distinct evidences of basilar tubercular meningitis. Heart: Normal; death occurring in strong systole. Lungs: Adhesions at both apices, and abundant deposit of tubercle in both lungs; old inflammation at right apex. Kidneys: Small; capsule not adherent; tubercles also found, but not excessive; also evidence of catarrhal inflammation. Larynx: Marked thickening and induration of epiglottis, aryteno-epiglottidean folds and cartilages; tuberculous ulceration at base of fold on left side. Testicles: Enlarged and presenting evidence of tubercular infiltration.

The specimen secured consists of the first, second, third, and fourth lumbar vertebræ, the spine being sawn in two with the spinous processes to the right. The corresponding half the family would not allow to be taken.

Dr. Janeway said the specimen had interested him a good deal, because he saw the patient early after the receipt of the injury and gave him a very careful examination. At first the question arose whether the symptoms were due to the irritation accompanying spinal meningitis, or to disease of the cord, or to disease of the vertebræ. At the patient's third visit Dr. Janeway found the phenomena of spinal caries so well marked, that is, pain on pressure on the top of the head, rigidity of the muscles of the leg, etc., that he recommended fixation of the spine, and sent the patient to Dr. Sayre. The point of interest in the case was the diversity of opinion concerning the nature of the affection which obtained at the trial, and the fact that three neurologists and surgeons had absolutely denied that there was any organic disease of the spine.

The President referred to a case which came under his observation, that of a man who was caught under an elevator and received a fracture of one or two vertebræ. In that case there were symptoms of myelitis, paralysis of the muscles of the leg, bladder, and rectum, which lasted for a long time. It was now nearly two years since the occurrence of the accident, and the patient was almost completely recovered, after having been treated by mechanical appliance, giving support from the hips and under the axilla, and extension made by screw and ratchet.

EXPERIMENTAL RESEARCH IN ETHER NARCOSIS.

Dr. R. W. Amidon presented the viscera of a cat which had died in a condition of narcosis from inhalation of ether. Five hours after the animal's death the right auricle contracted under the influence of mechanical irritation, as was demonstrated to the Society by quickly snapping the right side of the heart with the end of the finger. According to Dr. Amidon's observations ether kills a cat in about ten minutes, with shallow respiration and a continuation of the cardiac pulsation one or two minutes after respirations have ceased. The heart ceases to beat in diastole on the right side and in systole on the left side. The abdominal viscera are very much congested, especially the liver. The kidneys are almost of stony hardness, especially in the pyramidal portion. The spleen is congested. The lungs are usually normal; they are neither excessively congested nor œdematous. The abdominal, thoracic, and cervical veins are excessively distended with blood. The brain and spinal cord are apparently normal.

Dr. Amidon remarked that his experiments were made for the following purpose: It had been laid down in many text-books in surgery that ether-death was not always caused by asphyxia, but by heart-failure. In no case which he had studied had heart-failure been a primary factor. The anatomical appearances had been those of asphyxia, and he submitted the results of his experiments to the Society.

The indication in ether narcosis was, according to the result of his experiments, to start respiration and unload the right side of the heart, and the best method of accomplishing this was by artificial respiration accompanied by the administration of atropine, as he had set forth in a recently published paper.

Dr. Janeway remarked that he had heretofore directed attention to the indication for drawing off blood from the right heart with the hypodermic needle in certain cases, and in a few instances he had resorted to that procedure, but he had not yet been prepared to publish the result of his observations. He supposed it quite probable that in the great majority of cases of death from ether the fatal result was due to aspiration of food into the larynx and trachea.

The President referred to a case in which the woman was practically dead for fifteen minutes, and in which the suspension of animation was produced by a blood-clot in the larynx.

Dr. Gerster referred to one case in which death was caused immediately by the ether. It was that of a woman thirty-five years of age, with a large and simple hypertrophy of the thyroid body which pressed upon the trachea, causing dyspnœa by stenosis, and she also suffered from chronic catarrhal pneumonia of both sides, which greatly increased the dyspnœa. He decided, in spite of the large goitre, to perform tracheotomy to relieve the dyspnœa. The patient was anæsthetized with ether, and did not receive more than four or five whiffs before she became unconscious. The pulse and respiration going on, the incision was made with the knife and thermal cautery, but during the operation the pulse and respiration ceased and the face of the patient presented the appearance of one in collapse. Tracheotomy was

rapidly completed, and one or two shallow respirations took place, but the patient was dead. At the autopsy there was found extensive involvement of both lungs, and fatty heart with insufficiency of the tricuspid valves.

Dr. Amidon remarked with reference to aspiration of the right side of the heart, that he had seen animals apparently dead from ether narcosis, and the heart had begun to beat again after free incision in a large vein or in the liver, and allow it to be partially evacuated. He had suggested in his paper that free venesection might be a powerful adjuvant in the treatment of these cases. He would ask the surgeons present if they had noticed any difference in the effect produced by ether when Esmarch's bandage had been used; that is, whether the patient came under its influence more or less rapidly, and whether there was more or less liability to accidents.

Dr. Gerster said he had not observed any case with special reference to these points. With reference, however, to the propriety of artificial respiration, which he indorsed thoroughly, he might relate a case in which the heart had ceased entirely to beat, as the result of entrance of air into the pleural cavity. The case was one in which the pleural cavity was opened by an operation for the removal of a morbid growth, and as soon as the lung was subjected to the influence of atmospheric air the heart's action and respiration ceased, but were immediately restored by closure of the opening.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. LUND'S LECTURES AT THE COLLEGE OF SURGEONS—CASES OF RETENTION OF URINE—DR. MATHEWS DUNCAN ON RETENTION OF FÆCES—PUNCTURE OF THE BLADDER—VESICAL CALCULI—THE INTERNATIONAL SANITARY CONFERENCE AND QUARANTINE—THE DUST-BIN NUISANCE—THE NEW NOMENCLATURE OF DISEASES, AND SOME OF THE CHANGES FOUND IN IT.

London, June 23, 1885.

Mr. Lund, Professor of Surgery in the Victoria University, is nothing if not practical, and has set a useful precedent in his lectures just delivered at the College of Surgeons. Doubtless many of those who attend the College lectures have become tired of long set orations. Mr. Lund has adopted a different method, and, instead of confining himself to one subject, has given a number of interesting and practical remarks on various surgical subjects.

In his second lecture he spoke of some genito-urinary troubles. Referring to a topic which cannot be too often brought before practitioners, viz., retention of urine, Mr. Lund mentioned three striking cases. One was that of a young lady in whose case he was called in consultation to perform paracentesis: retention of urine was found. Another was that of an elderly man, with what was supposed to be a pelvic tumor pressing on the rectum, and causing tenesmus and difficulty in defecation. A quart of urine was drawn off, and the urgent symptoms soon disappeared. Another case was that of an elderly gentleman, who was suddenly seized with giddiness and rigors while at work in his office. Profuse perspiration came on. He went to bed and vomited. The abdomen was distended, and hernia was suspected. Mr. Lund catheterized and removed five pints of urine. Mr. Lund's second case reminded me of one recorded in Dr. Mathews Duncan's "Clinical Lectures." Dr. Duncan was sent for to pay a "satisfaction" visit to a patient said to be dying with malignant disease of the rectum. He was told that the growth could be felt in the iliac region, so far had it advanced. On examination the case was found to be one of enormous fecal accumulation in the bowel. On "digging" this out, the symptoms disappeared.

When puncture of the bladder is required, Mr. Lund prefers the suprapubic method. "It is," he says, "cleaner, and an instrument can more easily be retained."

In infants, circumcision should always be performed, he thinks, when the prepuce "balloons out" during micturition. Otherwise the straining tends to cause inguinal hernia. When a hernia has been produced Mr. Lund prefers the "worsted truss."

A case of vesical calculus was described in which the symptoms of stone were marked by enlargement of the prostate. The stone was kept from pressure on the collapse of the bladder, and perhaps kept in one place by its shape, it having become moulded to the neck of the bladder above the base of the prostate. Another case was mentioned in which the converse occurred, viz., a stricture far back in the membranous urethra caused such dilatation of the prostatic portion as to set up symptoms of calculus, which subsided on division of the stricture. An interesting case was referred to by the lecturer, in which a "click" was heard on introducing a metallic catheter into a woman's bladder, after a sound had failed in producing any. It was afterward found that this only occurred when the stream of urine was stopped by placing the finger on the mouth of the catheter. The bladder possessed great expulsive power, and while the urine flowed freely there was no sound.

The decision in favor of quarantine lately pronounced by the International Sanitary Conference, sitting in Rome, has caused great dissatisfaction here. The British members of the Conference were strongly against quarantine, believing it to be useless. It is thought that, in the event of five days' quarantine being imposed on vessels passing through the Suez Canal, many British shipowners will send their vessels by the old route round the Cape of Good Hope, so as to avoid the delay in the canal and also the canal dues.

A few years ago sanitarians were very indignant to learn that a large dust-sifting yard immediately adjoined the filter-beds of one of the London water companies. To this yard quantities of dust were daily brought and sifted, etc., with effects which may be imagined, especially when a strong wind blew in the direction of the filter-beds. The contents of our dust-bins, too, rarely consist of dust and ashes alone. Few householders trouble their heads about the state of the dust-bin, and the consequence is that all manner of rubbish and garbage is placed therein by servants. The wealthier the district the more the nuisance generally, because the servants are left more "to work their own sweet will." Add to this that it is a chronic complaint among householders that the dustman will not call except at infrequent intervals, and some idea may be formed of the decomposing mass which is daily shot down in the dust-yard mentioned. After letting the nuisance go on for years the Water Company have (in a bill now before Parliament) sought powers to purchase the yard from the Brighton Railway Company, who own it. The Select Committee of the House of Lords have, however, thrown out this clause on the opposition of the Railway Company. So all is to go on as before. Our boasted sanitary laws seem somehow often to fail us just when they are most wanted.

London, June 29, 1885.

The first revision, or second edition, of the official "Nomenclature of Diseases" has just been issued, and is in process of distribution to the profession. I have been able to obtain an early copy and look through it with some care. I subjoin some notes of the changes found. They are more numerous and extensive than might, perhaps, have been expected. Sixteen years have, however, elapsed since the first appearance of the work, and during this period the advance in all branches of the medical sciences has not been small. The actual revision has occupied nearly five years.

A very useful "Enumeration of Morbid States and

Processes" is now prefixed to the whole work. This is a modification of the list prefixed in the first edition to the sections on "Local Diseases," but now precedes the section on "General Diseases," "on the ground that its constituents are in various associations the elements of all the diseases subsequently tabulated." It is suggested in the preface that this table may form, in conjunction with the other sections, the basis of a cross-tabulation "in which the horizontal lines of this alphabet may cut the vertical lines of an anatomical alphabet."

The section formerly entitled "General Diseases" is now named "Diseases of the Whole Body," and diseases which may be distributed in several parts at one time, "General Diseases."

This section is divided into four groups—*A*, *B*, *C*, *D*.

Group *A* includes the specific febrile diseases, which are arranged in five subgroups. The first point noticeable under individual diseases is that all definitions are now omitted, which is indeed the case throughout the work. No varieties of small-pox or scarlatina are now given. German measles is introduced under the name "Epidemic Rose-rash." Under "Enteric Fever," there is a note that when occurring in children it should not be returned as "infantile remittent fever." Typho-malarial fever is introduced as a variety of enteric fever. "Choleraic Diarrhœa" is replaced by "Epidemic Diarrhœa." The terms "ague" and "remittent fever" are removed, and in their place is given "Malarial Fever: *a*, Intermittent; *b*, Remittent; *c*, Malarial Cachexia." Diphtheritic paralysis is now placed among nervous affections. Equiniamitis has disappeared, but horse-pox has been introduced. Malignant pustule gives place to splenic fever. Anthrax is no longer given as an equivalent for splenic fever, but is reserved as a synonyme for carbuncle. Sloughing phagedæna and hospital gangrene do not now appear as distinct affections, but simply as varieties of phagedæna. Puerperal fever is no longer to be used to describe puerperal pyæmia, septicæmia, or erysipelas, but the latter terms are to be employed. The only varieties of syphilis now enumerated under the heading "Syphilis" are, "*a*, Primary, Hard-chancre, or Infecting Sore; *b*, Secondary, or Constitutional." [In the first edition syphilis included soft-chancre, suppurating bubo, phagedænic sore, sloughing sore.] Lupus and ergotism vanish from the list of general affections, the former finding a place among skin diseases, the latter among poisons. Only two forms of rheumatism are now mentioned, viz., rheumatic fever and rheumatism. The latter term includes the subacute and chronic varieties. Gonorrhœal rheumatism finds a place amongst joint-affections. Gout is no longer divided into acute and chronic. Osteo-arthritis loses its former prefix of "chronic." Hydrophobia is now classed as a general disease instead of a nervous affection. Scurvy and alcoholism form, along with surfeit and starvation, Subgroup 4 of "General Diseases," viz., "Diseases Produced by Errors of Diet." Delirium tremens has been removed from the list of nervous diseases and placed as a variety of alcoholism. Myxædema, glycosuria, hæmophilia, and pernicious anæmia, may all be noted as additions. Leucocythæmia is also new to this section, though not to the whole work, it having formerly been classed as a splenic disorder. Tubercle now stands alone, instead of as a variety of scrofula.

Diabetes is now named diabetes mellitus (under renal affections we now find diabetes insipidus). True leprosy now figures simply as leprosy, and two varieties of it are now mentioned, viz., the tubercular and anæsthetic forms.

Considerable changes are made among the local diseases. Of these some of the most important are among the nervous diseases. The term sclerosis is now for the first time introduced, and three varieties are recognized, viz.: 1, Insular or disseminated; 2, diffuse; 3, miliary. Its varying distributions are thus given: *a*, Of the anterior cornua of the gray matter of the spinal cord (progressive muscular atrophy); *b*, of the lateral columns (spastic spinal paralysis); *c*, of the posterior columns (locomotor ataxy). The following are additions to this section: Opthalmoplegia externa (interna is not referred to), glosso-labio-pharyngeal paralysis, acute ascending paralysis, paralysis after acute disease (diphtheritic paralysis being given as a variety of this), pseudo-hypertrophic paralysis, toxic paralysis (lead palsy is given under this with drop-wrist as a variety of it), aphasia, dumbness (included in last edition, but placed under "Diseases Manifested at or soon after Birth"), somnambulism, megrim, and hystero-epilepsy (as a variety of hysteria); Ménière's disease (as a variety of vertigo), and hemichorea (as a variety of chorea), the division of chorea into acute and chronic being at the same time abandoned. Epileptic vertigo, or *petit mal*, is no longer recognized as a variety of epilepsy. Paralysis agitans displaces the term shaking palsy, and convulsions gives way to eclampsia, and in a note it is stated that when the cause is known the return should be made under the head of that cause.

Hypochondriasis, which formerly appeared as the last among functional nervous disorders, now leads the way among disorders of the intellect. The term insanity comes next, and now appears for the first time. A note states that this term should be employed only when the case does not manifestly come under the heads of one of the affections afterward enumerated. Imbecility no longer finds a place as a heading. Congenital imbecility is given as a synonyme for idiocy, and acquired imbecility is included under dementia. The latter is no longer divided into acute and chronic. The following headings are all new to this section: Puerperal Insanity, Epileptic i., Insanity of Puberty, Climacteric i., Senile i., Toxic i. (from alcohol, gout, lead, etc.), Traumatic i., insanity associated with obvious morbid change or changes in the brain, and finally consecutive insanity, from fevers, visceral inflammations, etc.

The classification of ocular affections is much more full and complete. Serous, gouty, and sympathetic forms of iritis are now added, and tubercular takes the place of scrofulous iritis. Keratitis is now more clearly divided into varieties, vascular keratitis being now recognized, and two forms of this, viz.: 1, Pannus; 2, deep vascular keratitis. Retinitis and glaucoma are each now divided into varieties. Cataract is more scientifically subdivided. Various forms of squint are now given. Protrusion of the eye-ball is now named proptosis. Among additions may be noted the following: myosis, mydriasis, synechiæ, iridoplegia, nystagmus, epiphora, and diseases of the optic nerve.

Under heart-diseases, hæmo-, hydro-, and pneumo-pericardium now gain admittance to the volume. The diseases of the peri- and endo-cardium are now given together as "diseases of the membranes." Suppurative pericarditis is now given as a variety of pericarditis, and pyæmic pericarditis is also added in the same place. Tubercular peritonitis is omitted, but tubercle is given as a separate heading. Periarteritis and endarteritis are now given as varieties of arteritis, but we look in vain for endarteritis obliterans. Syphilitic disease and parasites are added to the list of cardiac affections. The arterial degenerations are now given together as varieties under the heading "Degeneration." Fatty degeneration distinct from atheroma is not recognized. Under aneurisms we now get dissecting and miliary as varieties in addition to the three previously given, viz., fusiform, saccular, and diffused.

Turning to respiratory diseases, croup still retains its place, although many British pathologists and physcians strongly maintain its identity with diphtheria. Three forms of laryngitis are now given, viz., acute, chronic, and catarrhal, the latter being now introduced. Perichondritis is placed as a variety of inflammation of the larnyx. Bronchitis was formerly divided simply into acute and chronic; two new varieties now appear as well, viz., catarrhal and plastic.

Hæmoptysis formerly appeared as a variety of three affections, viz., passive congestion, pulmonary extravasation (p. apoplexy), and also among the general diseases under Phthisis, the latter disease being given under "Scrofula" as a local scrofulous affection. Passive congestion now stands alone. Hæmorrhage appears as a new heading, and hæmoptysis and pulmonary apoplexy are given as varieties of it. The terms acute pneumonic phthisis and chronic pneumonic phthisis remain as in the former edition, but the terms phthisis and acute miliary tuberculosis are now removed. They formerly appeared in the section on General Diseases, with a cross-reference to them in this section. There is now a cross-reference to the new heading, "Tubercle," in the section on General Diseases, and a note that the return is to be made according to a table on a subsequent page (under Tumors), which has been drawn up by Dr. Bristowe. In this table tubercles are divided into gray and white. Four varieties of each are given, viz., simple, inflammatory, ulcerative and destructive, retrograde and cicatricial. Pneumonia is divided into lobar and lobular, and croupous and catarrhal are added as synonymes. Syphilis (of the lung) is now inserted in place of the old term syphilitic deposit.

The inflammatory affections of the intestines are now given under a new heading—Inflammation—three varieties being enumerated, viz., catarrhal, diphtheritic, and ulcerative (enteritis, typhlitis, and colitis given as three subvarieties of this). Post-peritoneal and omental are added to the varieties of hernia. Among hepatic disorders, cirrhosis and hepatitis no longer retain their positions as distinct headings. In their stead Inflammation is placed as a heading, and three forms are described, viz., hepatitis, perihepatitis, and cirrhosis, the latter again being divided into hobnail liver and hypertrophic cirrhosis. "Adhesions" now form a separate heading under peritoneal diseases, instead of being placed under Peritonitis. Perityphlitis is not mentioned anywhere.

Hypertrophy, atrophy, and passive congestion (in diseases of heart and lungs) are added to the list of kidney affections. The nomenclature of renal disorders has undergone a great alteration. In the first edition "Bright's Disease" was given as a general heading and "Albuminuria" as a synonyme. Acute and chronic forms of Bright's disease were recognized, and three varieties of the latter were made to exist according as the kidney was granular, fatty, or lardaceous. Acute nephritis is now separated from Bright's disease, and forms a heading by itself, "glomerular nephritis" being named as a variety of it. Lardaceous kidney is also placed apart, and the only two forms of Bright's disease now acknowledged are: 1, chronic nephritis (chronic parenchymatous nephritis), and 2, granular kidney (chronic interstitial nephritis). Many will regret the separation of the lardaceous form. A new heading is now given, viz., Urinary Disorders. Suppression of urine is now placed under this heading instead of under kidney diseases. Here also are arranged the following new terms: Hæmaturia (in place of hæmaturia renalis), intermittent hæmaturia, chyluria, albuminuria, lithuria, oxaluria, and phosphuria. Diabetes insipidus also here finds a place, and a cross-reference to diabetes mellitus and glycosuria is prefixed to the list of urinary disorders.

The classification of vesical calculi remains virtually unaltered. Inflammatory stricture is now omitted as a variety.

Six varieties of ovarian cyst are now recognized. Inflammation and distention with blood are now added to the list of affections of the Fallopian tubes. The terms salpingitis and hæmatosalpinx are introduced as synonymes for the two preceding affections, and also hydrosalpinx as a synonyme for dropsy of the tube, but pyosalpinx has not been admitted. Instead of "Diseases of the Broad Ligaments," the heading now is "Diseases of the Uterine Ligaments, and of the Adjacent Peritonæum and Cellular Tissue." Under this heading are: hæmatocele, inflammation, abscess, cyst, varix, thrombosis, and a cross-reference to non-malignant new growth. It is now recognized that hæmatocele may be either intra- or extra-peritoneal, and it is divided accordingly. Inflammation is divided into—*a*, Pelvic peritonitis (Perimetritis); *b*, Pelvic cellulitis (Parametritis); *c*, Lymphangitis. Subinvolution and hyperplasia are now given for the first time as varieties of hypertrophy of the uterus in addition to elongation of the cervix, which was the only variety previously given. Atrophy is now divided into two varieties, viz., superinvolution and senile atrophy. Inflammation of the uterus (including the cervix) is divided into catarrhal and granular. Metritis is given as a general synonyme for uterine inflammation, and endometritis as an equivalent for catarrhal inflammation. Distention of the uterus is now deemed worthy of recognition as a distinct affection, and is divided into three varieties, according as the distending agent is blood (hæmatometra), secretion (hydrometra), or pus (pyometra). Leucorrhœa no longer appears as merely a synonyme for uterine or vaginal catarrh, but as a distinct affection. Inflammation of the vagina is divided into catarrhal and gonorrhœal, an arrangement which is certainly open to objection on clinical grounds. Sterility, vaginismus, and dyspareunia are additions, the latter two affections being distinguished from each other. Vicarious menstruation is replaced by the term ectopic menstruation; two varieties are allowed of this, viz., vicarious and supplementary. The displacements of the gravid uterus are now (omitting inversion) made to correspond with those of the unimpregnated organ. Rheumatism of the uterus has been expunged. The section devoted to affections connected with pregnancy has been retained, although the preface states that it has been omitted. Ectopic gestation now occurs in place of extra-gestation, and is divided into six varieties. Cerebral hæmorrhage has been added to the causes of sudden death after delivery.

Hypertrophy of the bones is now divided into concentric and eccentric, osteoporosis being given as a synonyme of the latter. Osteo-myelitis is now classified as a variety of osteitis, and osteitis deformans and perichondritis are also now added as varieties. Necrosis is divided into central and intra-osseous. Fatty degeneration of bone appears as a new affection. Three forms of ankylosis are now enumerated. Charcot's disease is set down among joint affections, with a direction to return cases of it under locomotor ataxy.

HOW TO REMEDY THE GROWING ABUSE OF MEDICAL CHARITY.

To the Editor of The Medical Record.

Sir: The recent exposure made by the Charity Aid Association, of the high percentage of unworthy patients treated in one of the largest and most carefully managed medical charities of this city, should lead the managers of all like charities to the work of looking into the facts of how this munificence is being expended. It has been, and is now, the practice in every institution in this city, open for the relief of the sick poor, to treat all who may apply without question, so that none may suffer; but this has been abused shamefully and to the extent that it is honorable now to ask and accept medical alms by anyone, whatsoever his or her station in life may be. Now all will agree unless the few who wish to take advantage of the humanely disposed for selfish ends that this is not right, and tends to cultivate a spirit in society which should be suppressed, and if necessary by vigorous means. And now comes the question, How can it be done?

To make it effective, the means employed certainly should be applied uniformly to every institution dispensing such aid. If it were otherwise; the unworthy applicants would go from the one refusing to another which would ask no questions. The plan of posting in the institutions the notice in full view, "*Only for sick poor*," has had no effect, for in another like institution it will be

confronted by a notice, "*Medicine and medical aid furnished for one dollar a month*" to all applicants, and depends on the personal pride and honor of the patients to forbid frauds. This plan we all know has not succeeded, but has rather cultivated this alms-receiving tendency to the extent that it is now expected as a right, by the unworthy as well as the worthy. The most feasible method for preventing this growing evil which occurs to me is to arrest it at the institution—to make it by law a misdemeanor for any institution to so indiscriminately dispense alms. Surely this is reasonable. The city which has been so munificent in its gifts to all such societies would favor, I am certain, this step and hail it as one in the right direction. Private parties who give of their means, whether it be in either large or small amounts, do so always with the impression that the sum will be used by the trustees wisely, and where it is needed, and only there; if in any other manner, they will consider that the funds intrusted have been misused and turned from their legitimate channel.

I therefore suggest that every charity institution should be prohibited by law, under penalty, from giving this aid to these applicants, unless they are known to be worthy or recommended as such by responsible parties.

ALEXANDER HADDEN, M.D.

[Dr. Hadden has had such a long experience in hospital and dispensary practice that his suggestions merit more than ordinary consideration. It is to be hoped that the managers of charitable institutions will give that attention to the subject that its importance demands. If they will not move in the matter the profession will. The rank and file of practitioners in this city are in earnest in their endeavors to check an evil which now has grown to monstrous proportions, and which threatens the bread and butter of everyone who is willing to work honestly and legitimately.—ED.]

RUPTURE OF THE PERINEUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of the 20th inst., Dr. Frank H. Hamilton, in an article entitled "A Few Practical Remarks on Rupture of the Perineum," maintains, if I understand him, that any manual interference with the natural process of labor, looking toward the preservation of the perineum from rupture, is, as a rule, not only useless, but may be hazardous.

I cannot agree with him.

Leaving out for the present the consideration of cases in which rupture results from malformations, cicatrices, unusual size of child's head, etc., I think it safe to say that tearing of the parts in question is almost always not only avoidable, but its occurrence is frequently a serious reflection on the medical attendant.

In the lying-in wards of Professors Spaeth and Carl Braun, at the General Hospital, Vienna, the writer has seen many perineums preserved, has saved many himself, and is, therefore, able, from observation and personal experience, to bear witness to the usefulness of this practice. The more simple measures failing, recourse should be had to episiotomy—that is, incising the margin of the vulva on one or both sides, thus enlarging the outlet. Such incisions heal quickly, and, as compared with perineal rupture, are altogether insignificant. And this episiotomy is a very necessary measure when, after the outlet is distended to its full capacity and rupture is imminent, there remains no alternative but laceration. Of two evils the less should be chosen. Dr. Hamilton's cases, in which he has seen the perineum stretch to the thinness of paper and then suddenly give way, possibly might have been saved had an episiotomy been performed. The statistics of the Vienna Hospital[1] show that, by proper care, ruptures may be reduced to a small fraction of one per cent., whereas writers on obstetrics have claimed ten or fifteen per cent. unavoidable.

[1] American Journal of Obstetrics, vol. xviii., No. 3, p. 233.

What, then, are the appropriate means for preserving the perineum? Certainly not simple pressure against that structure, for such practice would not only be indeed useless, but absurd. Other means must be resorted to, the objective point being to gradually stretch the outlet so that the head may be safely expelled, which is accomplished by allowing the head to descend again and again hard against the perineum; in this way that structure is not taken by surprise, and the head is prevented from a too early and sudden tearing through of undilated parts. This is very practicable, though it sometimes requires all the available muscular strength of the accoucheur. Then, at last, after full dilatation of the outlet, if it be found impossible to deliver the head without a laceration, an episiotomy should be made, and for that purpose a bistoury should be at hand in anticipation of such a contingency.

The theory is easily understood, but practice alone can perfect the art. For ease and convenience the woman should be delivered on the left side. As she lies obliquely across the bed with the hips on the right edge, the nurse supporting the raised right knee, the physician sits behind, his left hand between the thighs and covering the vulva; the right, with a towel intervening, over the perineum, though never hiding it from view. As the head is pushed down by the uterine contractions and the voluntary efforts of the woman, it is held from advancing too far, if necessary, by clasping the hands firmly against it. When the head has advanced far enough and the parts are sufficiently dilated, it is slowly and carefully shelled out between the pains, the woman assisting, if necessary, by voluntary expulsive efforts, as directed by the physician. Care should then be taken that the shoulders do not cause the injury the head has been prevented from producing. The writer is convinced that he has in this manner prevented a considerable number of otherwise unavoidable ruptures, and he confidently recommends such practice.

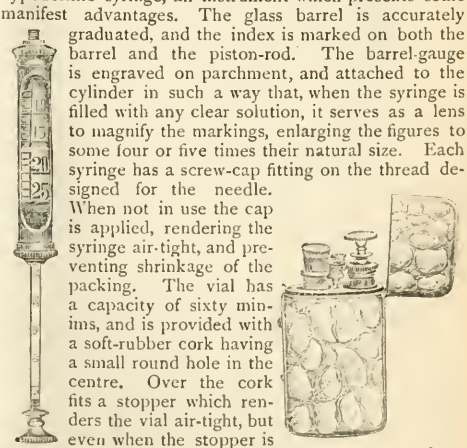
S. A. RUSSELL, M.D.

135 NORTH PEARL STREET, ALBANY, N. Y.,
June 24, 1885.

New Instruments.

A MODIFIED HYPODERMIC SYRINGE.

THE accompanying illustration represents the "Farny" hypodermic syringe, an instrument which presents some manifest advantages. The glass barrel is accurately graduated, and the index is marked on both the barrel and the piston-rod. The barrel-gauge is engraved on parchment, and attached to the cylinder in such a way that, when the syringe is filled with any clear solution, it serves as a lens to magnify the markings, enlarging the figures to some four or five times their natural size. Each syringe has a screw-cap fitting on the thread designed for the needle. When not in use the cap is applied, rendering the syringe air-tight, and preventing shrinkage of the packing. The vial has a capacity of sixty minims, and is provided with a soft-rubber cork having a small round hole in the centre. Over the cork fits a stopper which renders the vial air-tight, but even when the stopper is off the bottle may be laid down on the table, and no fluid will escape through the centre hole. To fill the syringe from the bottle, the needle should be inserted through the rubber cork, and the shoulder held firmly,

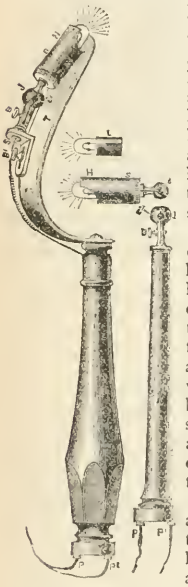


stopping up the opening. Then the piston, which had previously been drawn out, should be pushed home, thus forming a layer of compressed air above the fluid. Then, when the piston is again withdrawn, the pressure within the vial and the vacuum within the cylinder will cause the fluid to enter the syringe at once, without wasting a drop. The case, as represented in the figure, is made of plated metal, and contains the syringe, vial, two needles, and a bunch of wire. All of these are held in position by springs, so as to prevent spilling when the case is opened. It is manufactured by F. A. Reichardt, of this city.

ELECTRIC ILLUMINATORS FOR EXAMINING VARIOUS CAVITIES OF THE HUMAN BODY.

INVENTED AND MANUFACTURED BY CURT W. MEYER, NEW YORK.

THE electric illuminator for the mouth and throat consists of a combination as shown in the illustration below, viz.: A novel form of tongue-depressor *T*, with an insulating handle attached, through which the conducting wires are passed to connect with the battery cords at *P P'*; an electric incandescent lamp *L*, mounted and set into a shield-tube *H* (a non-conductor of heat), with a double conducting ball-joint movement *J*, and an adjustable slide *S* which holds the lamp, and which is held firm to the tongue-depressor by a set-screw *B'*.



It will be seen at once that every desired movement of the lamp has been provided for. The lamp may be set firm by pressure of the binding screw *B'*; further, the position of the lamp on the tongue-depressor can be changed, as it will slide back and forward. The lamp can be instantly brought in broken circuit at *i'* by slightly turning the lamp-tube *H*, and the latter with its ball-joint can be at once detached from the tongue-depressor.

The lamp now can be set into another insulating handle (forming the universal illuminator) at *J*, if the light is to be used for further examinations. The mounted lamp can be removed from the shield-tube *H*, if necessary, by pushing it out of the tube through slot *S*. A duplicate mounted lamp, also a mouth-mirror with handle, are added to complete this set of instruments, which are fitted in a finely finished pocket-case lined with velvet.

These instruments in their present form will be found to be an invaluable assistant to physicians and dentists, and their substantial workmanship will make them a lasting apparatus.

PROFESSOR ZWEIFEL ON RULES OF MEDICAL BEHAVIOR.—Dr. Albert S. Adler, of Solomonville, A. T., sends us some criticisms on the astute and popular author of "The Physician Himself," concluding with the following: "I remember but too well the words of the eminent Professor Zweifel in Erlangen, 'that rules in regard to medical toil and human delicacy are the acquisitions of a general education, and for this very reason words would be superfluous to the one, to the other useless. He who does not possess the intelligence to learn quickly from the example set by his preceptor, can never gain it by the medium of words.'"

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 4, 1885, to July 11, 1885.

HAVARD, VALERY, Captain and Assistant Surgeon. Assigned to duty at Fort Wadsworth, New York Harbor. S. O. 140, Department of the East, July 2, 1885.

WYETH, M. C., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Wayne, Mich. S. O. 140, Department of the East, July 2, 1885.

POWELL, JUNIUS L., Captain and Assistant Surgeon. Ordered from Department of the East to Department of the Missouri. S. O. 155, A. G. O., July 9, 1885.

BIRMINGHAM, HENRY P., First Lieutenant and Assistant Surgeon. Ordered from Department of the Missouri to the Department of the East. S. O. 155, A. G. O., July 9, 1885.

Official List of Changes in the Medical Corps of the Navy for the week ending July 11, 1885.

BYRNES, J. C., Passed Assistant Surgeon. Detached from the Powhatan for duty at Navy Yard, Norfolk, Va.

CORDEIRO, F. J. B., Assistant Surgeon. To the Powhatan as relief of Passed Assistant Surgeon Byrnes.

CURTIS, L. W., Assistant Surgeon. To Philadelphia for examination preliminary to promotion.

DRENNAN, M. C., Surgeon. Placed on waiting orders.

FITZSIMMONS, P., Surgeon. Duty on Receiving Ship Franklin, Norfolk Navy Yard, continued until July 1, 1886.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, for the two weeks ending July 11, 1885.

FESSENDEN, C. S. D., Surgeon. Leave of absence extended sixteen days, on account of sickness, July 1 and 9, 1885.

BENNETT, P. H., Assistant Surgeon. Granted leave of absence for twenty-two days, July 9, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 27, 1885:

AN ENGLISH SURGEON ON VIVISECTION.—Is it simply an impenetrable dulness which causes a man of surgical education like Mr. Lawson Tait to make such a statement as the following, at a recent meeting of the English Anti-vivisection Society: "I am quite sure," he said, "that many even of the vivisectors themselves will come to the conclusion which the lessons of surgery and pathology have taught me, that vivisection is not only useless in solving riddles such as we have to deal with, but that it is absolutely misleading."

THE ACRO-NEUROSES.

FUNCTIONAL NERVOUS AFFECTIONS OF THE EXTREMITIES.

BY C. L. DANA, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL; PROFESSOR OF PHYSIOLOGY, WOMAN'S MEDICAL COLLEGE OF NEW YORK.

(Concluded from page 58.)

SENSORY DISTURBANCES.—These are known under the names of paræsthesia, ignipedites, acrodynia, neuralgia, hyperæsthesia, pododynia, tarsalgia, hyperæsthesia.

Paræsthesia.—Under the head of paræsthesia are included the sensations of prickling, numbness, burning, etc., which are familiar to every physician. Some have given a special name to that variety of paræsthesia in which there is an intense burning sensation. Mitchell calls it causalgia, and finds it to be the result of nerve injury. In the multiple neuritis of alcoholism, beri-beri, acrodynia, and ignipedites, this symptom is a very prominent one. Hence it is safe to say that an intense persistent burning sensation indicates some organic peripheral nerve trouble. We can hardly say this of the milder "burning sensations," which are simply to be classed with ordinary rheumatic or neurasthenic "paræsthesia." This ordinary type of functional paræsthesia has been well observed and described by Drs. Ormerod, Wharton Sinkler, Weir Mitchell, and J. J. Putnam. It occurs oftenest in women, and at about the time of the climacteric. The patients experience annoying sensations of numbness, prickling, or burning in the hands, arms, or, perhaps, feet. The symptoms are worse at night, but generally continue through the daytime. There may be a slight loss of power in the arms.

I have notes of thirty-one cases of this trouble. Of these the burning sensation was the most complained of in eight.

CASE IV.—Mrs. Mary A——, aged thirty-nine, came to me complaining bitterly of burning sensations in her hands and feet. These were worse at night, and sometimes kept her from sleep. She has always been "nervous," lately very much so, but has no hysterical history. She is slightly anæmic, dyspeptic, and constipated. The extremities present no objective changes. She improved under local and general treatment.

Among the other cases the "burning" seems to have occurred in young and hysterical or in older neurasthenic and rheumatic women. In one case of ignipedites the cause was a change from wooden clogs to leather shoes.

A very severe type of the ordinary form of paræsthesia was the following:

CASE V.—Mary G——, a hard-working German woman, fifty-four years old, came to me complaining of prickling and numbness in the two hands and in one heel. The symptoms were much worse at night, and were so intense that she had to wrap her hands up in flannels, and could not sleep on account of the intolerable sensations. No anæsthesia, no objective changes in hands, urine normal, bowels regular, no rheumatism. Patient had been healthy, not nervous, had thirteen children. Under tr. nuc. vomic. she soon got well.

Of twenty-eight of my cases of paræsthesia available for analysis nine were among men, nineteen among women. The age in women ranged from nineteen years to sixty-six, most cases occurring between thirty-five and fifty-five. In men the average age was older.

In five cases there was a history of rheumatism, in eight of overwork and worry, alcoholism and sexual excess each brought on the symptom in one case. In the younger cases there was hysteria and anæmia. In eight cases it was unilateral. We may say in general that the purely neurotic type of paræsthesia is comparatively rare. I have met two examples of it.

CASE VI.—A gentleman about forty years old, a cotton-broker, was sent to me by my friend Dr. S. Baruch, suffering from paræsthesia of the left arm and hand. He felt an almost constant sensation of numbness, prickling, etc., extending up to the elbow. The symptom annoyed him to the last degree, the annoyance depending partly on the fact that he was afraid he was going to be paralyzed. There was no anæsthesia and no objective change in the hand and the patient was in good general health. He had been a great smoker. He left off smoking, but was no better. He was treated in various ways with but little improvement. He went to a well-known general practitioner, who gave him Warburg's tincture and said he would be well in eight days. He was not, but after several months, the cotton market getting easier, the affection gradually left him.

Paræsthesiæ of course occur in organic diseases of the nerve-centres or nerves. Sometimes, also, these symptoms are brought on by lead-poisoning (Putnam), or by arsenic (Seguin), or by alcohol or tobacco. These facts must be borne in mind in making a diagnosis. When the symptoms are very severe and persistent we should always suspect a toxic or infective neuritis. Many ordinary cases of ignipedites are caused mechanically by badly-fitting, or thin-soled shoes, or by long standing or walking.

The treatment for neurotic cases is in the use of strychnia, bromides, alkalies, and electricity, galvanism being, I think, far the most efficient form. For the rheumatic types, oil of gaultheria, potassium iodide, and electricity may be given. Hot and cold douches to the parts are often excellent. Of course, attention must be paid to general hygiene.[1]

Ignipedites, or "burning feet," technically speaking, is the name given to a disease observed among soldiers in India in the early part of this century, and first described by Dr. Grierson. The disease is a depressive, constitutional one, resembling in some respects, scurvy. Later investigations have shown its close relation with acrodynia, and beri-beri. In all three of these diseases

[1] *Causalgia* is a name suggested by Dr. Weir Mitchell for the burning sensations that occur as the result of nerve injury. The symptom is the result of peripheral nerve-lesions and cannot be spoken of as a neurosis.

an intense and agonizing burning in the soles of the feet and sometimes in the hands is observed. Beri-beri is known to be an infective multiple neuritis. Ignipedites is doubtless also caused by a neuritis.

Acrodynia (cheiropodalgia) is a term employed to designate a peculiar disease, generally epidemic and characterized by severe pains in the extremities. It was first observed as an epidemic in Paris in 1828. Later it occurred among the workmen in a fuchsin factory at Lyons in 1864, in the French Army of the East in 1854, and again among French soldiers in 1874. It broke out also in a convent of St. Bernard in 1846, and a disease very similar to it has been described in Italy and Spain.[1] It has occasionally occurred sporadically. Some have claimed it to be only the Italian disease pellagra; others, trichinosis. It seems, however, as I have stated, to be most allied to the ignipedites of the Indian soldiers and to beri-beri. It is characterized by severe pains and erythema of the extremities. This is accompanied with painful muscular contractions, and followed by paresis and anæsthesia. There are also marked digestive disturbances. The disease runs its course and the patients generally recover in a few weeks. It is probably an infectious multiple neuritis—a view suggested by Broussais.

Acrodynia is a disease which has not been observed in this country to my knowledge, although the term has been wrongly used to indicate a painful neuralgia of the finger (Pancoast, *Philadelphia Medical Times*, 1872).

Hyperæsthesiæ and neuralgiæ of the extremities.—Both feet and hands are subject to hyperæsthesia and to neuralgic pains. A hyperæsthetic condition may exist entirely apart from any paræsthesia and neuralgia, although these latter are generally associated with it.

Hyperæsthesia in a most marked form has been observed in chronic alcoholic poisoning. Plantar hyperæsthesia not rarely occurs as the result of mechanical causes, from wearing thin-soled or ill-fitting shoes.

Some cases of plantar hyperæsthesia in which the trouble appears to be a pure neurosis are reported. M. L. Barbillou has recently described cases of this kind (*Progrès Médicale*, 1885, p. 375). His cases, four in number, were observed in the service of M. Debove and Dr. Rueff. The patients were all men, without any neuropathic history, and gave no signs of organic disease, local or central. They had no pains in the feet, but simply an exquisite sensitiveness which made walking almost impossible. One patient had gonorrhœal rheumatism; in another, and I fear in all, alcoholism could not be positively excluded. All the patients were cured by blistering the feet or by congelations with Debove's chloride of methyl.

Neuralgias of the feet and hands.—These seem to be of two classes: Reflex neuralgias, and neuralgias due to some mechanical fault in the foot. Under this latter head come Morton's luxation neuralgia, and the so-called Tarsalgia, or Policeman's disease. It is a question whether there is such a disease as the pododynia or tailor's neuralgia, described by Gross in his "System of Surgery." I know no one who has ever seen it or reported a case. A form of neuralgia accompanied with spasmodic contracture of certain leg-muscles, described by Weir Mitchell, belongs apparently with the tarsalgia of the French writers. Besides these types, I have observed some curious forms of acro-neuralgia which it is difficult to classify.

Reflex neuralgias of the extremities are not rare.

One of the most distressing forms which I have seen was the following, occurring in a patient sent me by my friend, Dr. J. R. Nilsen:

Case VII.—*Reflex neuralgia of hands in a pregnant woman.*—Margaret M——, aged thirty-five, English. Has always been healthy, though of a nervous temperament. Has never had neuralgia before. Is now pregnant for the first time. Since about the third month she has suffered from pains in the fingers of both hands. The trouble began in the left hand, with a diffused pain affecting the fingers and thumb; the right hand then became involved. Pains ran up to the elbow at times; they were continual, day and night, so that she could not sleep; worse in warm weather. There was no local swelling, tenderness, vaso-motor disturbance, or sweating. Dynamometer, right hand, 28; left, 20. Sensation and muscular sense normal; no twitchings or cramps. Under anti-rheumatics no relief was obtained. Strychnine did no good, but under local galvanization and bromides she improved. This was undoubtedly a reflex uterine trouble, which will disappear after the birth of the child.

Dr. Nilsen tells me of a patient of his who suffered from ovarian irritation and prolapse. She had intense neuralgic pains in the wrist.

I am treating now a hysterical woman with paraparesis and painful spasms of the bladder. Every time she has the painful expulsions of urine an intense pain is felt in the palms of the hands.

Reflex pains in the feet are not so very uncommon. Dr. T. B. Curtis (*Boston Medical and Surgical Journal*, 1881, No. 14) has taken the trouble to collect all the causes of reflex pedal pain. They, almost all of them, consist in some form of irritation of the genito-urinary tract, *e.g.*, gonorrhœa, stricture of the urethra, vesical calculus, cysto-prostatitis, cystalgia, renal calculus.[1]

Neuralgic and other painful affections of the extremities due to mechanical cause.—One of the most interesting forms of pedal neuralgia is that described first by Dr. Morton, of Philadelphia, and called by him a "luxation neuralgia." It is a neuralgia affecting the metatarso-phalangeal joint of the third and fourth toes, and is due, it is thought, to a slight luxation, with consequent pressure on a digital branch of the external plantar nerve. Dr. Morton collected fifteen cases (*American Journal of the Medical Sciences*, 1876, n. s., lxxi., p. 37). A case has subsequently been reported by Dr. M. C. Kemper (*Virginia Medical Monthly*, 1881–82, vol. viii., p. 522). It occurs generally in women, and the cause is external injury or shoe-pressure. Treatment is not very satisfactory. It should be directed to giving rest to the foot, and the avoidance of lateral pressure on the joints by wearing a broad-soled shoe. Support may be given by a broad flannel bandage. Amputation of the toe has cured one case.

The following case seems to belong to this category:

Case VIII.—*Luxation podalgia (of Morton) in a woman fifty-five years of age.*—The patient has always been healthy, has had several children. Is thin, of nervous temperament, energetic, and hard-working. Has not had rheumatism or gout. Has acted as a nurse for several years past, and been on her feet a great deal. This, at times, caused plantar hyperæsthesia and neuralgia, relieved by rest. In past years has, at times, suffered from pains in third and fourth toes and metatarso-phalangeal joints of right foot. Cannot attribute it to injury or any cause except excessive standing and overwork.

In the last few months she has had most intolerable pain in the toes mentioned. They feel as though a rod of fire had been thrust into them. These pains come on her in the daytime when she is out walking. She is in such agony that she jambs her umbrella or parasol upon them. After getting home, taking off her shoes and stockings, and applying cold cloths, the pain is relieved.

Examination discovers no tenderness, swelling, or redness; no anæsthesia or hyperæsthesia, or any objective symptoms whatever.

The patient has normal urine and gives no gouty history. Nor is she relieved by anti-gout drugs, such as colchicum, iodides, and alkalies. Anodyne applications and rest helped her most.

Tarsalgia (*podalgia, policeman's disease*) is a neuralgic affection, due probably in most cases to an incipient flattening of the foot, and stretching of the plantar ligaments

[1] Described by San Marino in 1762 and called cheiropodynia; also observed by Nicoletti in 1806.

[1] Pedal pains occur in gout, rheumatism, syphilis, tabes, chronic alcoholism, and diabetes. The pains of latent gout, according to Anstie, are generally located in the dorsum of the foot. Those of chronic alcoholism have been observed to occur in the wrists and ankles. In syphilis a node can generally be discovered. A differential diagnosis is, therefore, quite possible.

Some have ascribed it to a deep-seated contusion of the adipose cushion covering the os calcis. Probably the condition varies somewhat in different cases. It is observed in persons who have been in the habit of going barefoot, and have then gone into the army or taken civil positions obliging them to stand or walk a great deal.

It occurs also in the policemen of Paris. Velpeau first observed it there in 1833, and gave it the name of the Policeman's disease. It has subsequently been described by other French writers, *e.g.*, Fabre, Desprès, and Gillette. The name tarsalgia was, I believe, given by Duchenne. Subsequently Gasselin, Lannelongue, and Le Fort have written about it. Only one case, so far as I know, has been described as Policeman's disease in this country, and that by Dr. T. B. Curtis, of Boston (vide *loc. cit.*). Dr. Curtis states that the policemen of Boston are not subject to it, and Dr. Morris N. Henry, of this city, kindly informs me that it has not been observed among New York policemen. This is due to the difference in the shoes and in the gait of American and Parisian guardians of the peace.

It appears to me that Dr. S. Weir Mitchell has described what is essentially this disease in the *Philadelphia Medical Times*, 1872, 1873, vol. iii., pp. 81, 113. At any rate, in tarsalgia, as in Mitchell's cases, there is not only pain in the heel and whole foot, but often contracture of the perineus longus, gastrocnemius, and plantar muscles.

If there is such a disease as the pododynia of Gross, Dr. Mitchell gives evidence to show that it is not confined to tailors, and that in some cases, at least, there is a low grade of arthritis of the small bones of the feet. Treatment, medical or surgical, seems to do little for the disorder, which is very chronic. Patients are better in cold weather, and when resting the feet.

Peculiar Neuralgic Affections.—A very peculiar vaso-motor and neuralgic affection of the hand was brought to my notice recently.

Case IX.—Charles C——, married, aged fifty-five. Has been a strong healthy man ; used tobacco but not alcohol ; no specific disease. Is a stamper, and has to use the right hand and forefinger a good deal. In past three or four months has had a constant dull pain in the right forefinger extending to the wrist. Worse at night and in damp weather. Is steadily getting worse, and he begins to feel pain now in the thumb. This is so bad that he has had to give up work. There is no burning sensation. The finger is objectively cold, pale, flabby, and evidently has an impaired circulation. There is no anæsthesia or analgesia, and no hyperæsthesia. No motor trouble or weakness. One application of faradism relieved the pain instantly. He was then lost sight of.

The following is a case of a chronic neuralgia of the hand apparently hysterical in character.

Case X.—Rebecca S——, aged thirty-four, New York. Parents healthy and had seventeen children. The patient is married and was well until she had her sixth and last child, a year and a half ago. She had been subjected to trouble and had worried a good deal. Is of a nervous temperament. After the last confinement she had puerperal mania for several months. She is now very nervous. Comes to complain of a painful finger which she has had for two years. The pain is in the outer side of the left middle finger, and runs up to the palm. There are no objective symptoms, no sensory or vaso-motor disturbances. The pain was intense, often preventing sleep.

Secretory Acro-neuroses.—*Moist or dripping hands* are frequently observed in persons of nervous temperament, whether men or women. Sometimes the palmar hyperidrosis is so great as to be very annoying, and patients apply simply for relief of this symptom. I recall two cases of this kind. The patients were both women, and at about the menopause. They had no organic disease, but complained of various vaso-motor disturbances, such as disagreeable flushings of the face, "rush of blood to the head," sensations of fever, etc. The hands were continually moist and almost dripping with perspiration. A moist, dripping hand is often observed after nerve injury. Many persons suffer all their lives with a disagreeable palmar and plantar hyperidrosis. The latter is often combined with bad odor, due to decomposition of sweat. In some persons who suffer from this latter complaint the condition is congenital. If the trouble comes on in youth or adult life it is because of some causes that have produced a depressive nervous state. The remedies here are, therefore, general tonic measures and careful local treatment, with the use of antiseptics and astringents as described in dermatological text-books. Unless the trouble is excessive I do not find that patients will carry out a treatment very long. Hydrobromic acid comes as near a specific as anything. Strychnine, quinine, and atropine, with regular mercurial purges, should also be tried.

TWO CASES OF BRANCHIAL CYST.

By HENRY DWIGHT CHAPIN, A.M., M.D.,

LECTURER ON DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL ; ATTENDING PHYSICIAN TO THE OUT-DOOR DEPARTMENT, BELLEVUE HOSPITAL (CHILDREN'S CLASS).

The infrequency with which this variety of congenital tumor of the neck is seen, and the desirability of recognizing its nature, both as regards prognosis and treatment, have led me to write an account of the following two cases. In the early part of March there was brought to my clinic at the Out-door Department of Bellevue Hospital, a baby, five days old, having a tumor as large as an orange on the right side of the neck, the sterno-cleido-mastoid muscle crossing it at about its centre. The tumor was somewhat fluctuating and without pain, as the baby gave no signs of discomfort while it was being freely handled. The skin over the swelling had a natural appearance, and there was an entire absence of any inflammatory conditions. Having in mind the possibility of a congenital hernia of the lung, I first applied a stethoscope to the swelling, but could only hear the tracheal sounds transmitted rather indistinctly. An aneurism was likewise excluded by this examination, as there was an absence of pulsation and no bruit heard ; it was likewise noted that pressure did not modify in any way the size of the tumor. At this age an aneurism would probably have been traumatic. An aspirating needle being introduced, some pale, straw-colored serous fluid was withdrawn, and the diagnosis made of congenital cyst.

Fig. 1.

When the baby cried the cyst would grow tense, and the sterno-cleido-mastoid muscle, by contracting, divided it into two parts, which, however, had free communication, as pressure was readily transmitted from one to the other. The cyst was apparently unilocular. At birth the tumor was about the size of a walnut, but it had

since grown rapidly to attain the present size, and bade fair to do harm by pressure upon the food- and air-passages, as it was continuing to increase in bulk. As the parents could not give the baby the requisite attention at home, I placed it under the charge of Professor Stephen Smith in his wards at Bellevue Hospital. The object of treatment in these cases is, of course, to radically destroy the membrane that secretes the serous contents of the tumor. In structure the cyst consists of a thin capsule of connective tissue, lined on its inner surface by a matrix of epithelial cells, which must be destroyed by an inflammation set up in the sac, or removed by the knife, before recovery can take place. As these cysts are frequently connected with the sheath of the deep cervical vessels, complete removal by operation may be attended by alarming, if not fatal, hemorrhage. It is thus best to try the former method first. When the infant entered the hospital a silk seton was introduced into the cyst. Very little discomfort or disturbance followed, although the temperature rose temporarily to 101°. As there was a very scanty discharge and scarcely any inflammation induced by this seton, two more were introduced in a week's time. The temperature rose to 102° for a few hours, but soon subsided. The three setons now gradually caused a thickening of the sac by a low grade of inflammation, although there was no external redness and apparently not much pain following their use. They were left in place for about three weeks, when it was determined to evacuate the cyst, as, although growth had ceased, it was not diminishing in size. The setons were accordingly removed, an opening made into the cyst, and a large quantity of straw-colored fluid evacuated. The cyst was then distended with a solution of carbolic acid (1 in 100), and antiseptic dressings applied. When the dressings were removed in a few days, it was found that the sac was well contracted, and that there had been a very slight serous discharge. Other dressings were applied and changed from time to time during the next few weeks. The sac showed no tendency to refill, but continued to shrink up, until there is now nothing present but a lump of connective tissue, that will probably be still further absorbed.

FIG. 2.

It is often the experience of physicians that when a rare case of any kind is met, another of like nature is soon encountered. This, at least, has been my good fortune in the matter of branchial cysts. A boy, eight years of age, was recently brought to me by his mother, to discover the nature of a peculiar swelling about the size of a hen's egg, situated under the right side of the lower jaw, and extending to the upper part of the neck. The boy was healthy-looking, and had never had any serious illness. Two months ago his mother noticed a small swelling in the situation just noted, which appeared rather suddenly—at least, she observed it first one morning after the night's rest. She says it seemed about the size of the end of an egg, but I think there must have been a mistake in reference to its sudden inception, as a small and rather soft tumor could readily be overlooked in the soft tissues of the neck. At any rate, it grew rapidly, but without pain. There was no history of a blow, but as the boy was a restless, active little fellow, his mother thinks he could sustain a slight contusion or knock without particularly noticing it. When I examined him, a very free manipulation of the tumor caused no discomfort. It was evidently cystic, which was proven by removing some bloody-looking serum through a hypodermic needle.

FIG. 3.

In the case of this boy the fetal epiblastic tissue remaining from the imperfect closure of one of the branchial clefts had evidently continued in an embryonal condition until his eighth year, when, possibly from some irritation, proliferation took place, and a sac was formed lined with epithelial tissue. These cysts may thus appear in after life, if the epithelial elements resulting from defective development are present, as the latter do not necessarily become active before or immediately after birth. I placed a silk seton in the middle of the cyst, which raised such an active inflammation as to necessitate its removal in three days. The irritation involved in this procedure proved sufficient, as the cyst grew smaller, and finally completely disappeared. There is now nothing left to mark its site but a small, hard lump that can be better felt than seen.

A glance at some of the facts of embryology, as developed by Cusset and others, will assist in a correct understanding of these branchial cysts.

Early in the fetal life of the vertebrata there appears under the projecting frontal process a series of four plates, bounding the cavity of the pharynx on the side. These plates unite to form four parallel arches separated by transverse clefts. The branchial clefts unite, and by a process of morphological change form various structures of the neck. If this regular process of development is interfered with from any cause, various abnormalities may result, as a condition intended to be merely temporary remains more or less permanent. Hence, according to the various grades of arrested development we may have marked deformities, branchial cysts, or the remains of fetal epithelial tissue, destined to proliferate at a later day and form a cyst. There likewise may result fistulous tracts from non-union of the branchial clefts, particularly from the lowest one. These have been divided into (*a*)

complete branchial fistulæ, open the whole length of the tract; (*b*) fistulæ having only an external orifice and ending in a cul-de-sac, which is the commonest form; (*c*) fistulæ with only an internal orifice.

More frequently the branchial tract is closed at both the pharyngeal and cutaneous ends, and a cyst is formed between. Branchial cysts, although rare, are hence more frequently met than fistulæ. In an excellent and exhaustive paper on "Branchial Cysts of the Neck," read before the American Medical Association at its meeting in 1884, by Dr. N. Senn, of Milwaukee, the following classification is made according to the cystic contents:

"1. Mucous branchial cysts, due to imperfect closure of the upper portion of the branchial tract with retention of its physiological secretion. 2. Atheromatous branchial cysts, usually located in the second and third branchial tracts in the region of the hyoid bone. 3. Serous branchial cysts, having a thin-walled capsule lined with pavement epithelium, and following the defective obliteration of any of the branchial clefts. 4. Hæmato-cysts of branchial clefts, in which the serous fluid of the cyst has been discolored by hemorrhages into the sac."

The second case mentioned in this paper is of the latter variety. While the contents of these cysts vary according to the branchial tract from which they are developed, yet they are always such as may be produced by some kind of epithelium, as only this variety of tissue is present at the time of closure of the branchial clefts. In this they differ from true dermoid cysts, that contain the secretion of the various glands and appendages of the skin. A simple serous cyst, developed in the connective tissue of the neck, independently of a branchial origin, will not have the lining of epithelial tissue. It was after a microscopical examination that I became satisfied of the branchial source of the boy's cyst. The photographs of the baby were made by Mr. Mason, of Bellevue Hospital.

29 West Forty-second Street

ABSCESS OF THE TONGUE; WITH REPORT OF A CASE.[1]

By CHARLES H. KNIGHT, M.D.,

Assistant Surgeon Manhattan Eye and Ear Hospital.

The tongue is essentially a muscular organ with a rich vascular supply. Its medullary portion is made up of fibres of the palato-glossus, stylo-glossus, and genio-glossus muscles. Its arteries are derived from the lingual branch of the external carotid. The hypoglossal is the motor nerve of the whole tongue. The anterior portion of the tongue, lying in front of the circumvallate papillæ, has its sensory supply from the lingual branch of the inferior maxillary nerve, accompanied by filaments of the chorda tympani; its posterior third receives the glosso-pharyngeal nerve. The latter region is furnished with numerous glands and is much more lax in structure. Its remarkable immunity from phlegmonous inflammation is, no doubt, explained by the scarcity of cellular tissue in the composition of the tongue.

That abscess of the tongue is a rare affection is in a measure indicated by the absence of reported cases from surgical literature. Fairlie Clarke, whose work on diseases of the tongue is perhaps the leading authority, mentioned but three cases reported by various observers. Gross and Agnew agree in the opinion that the structure of the organ is unfavorable to suppuration, even when an extreme degree of inflammation exists. In Holmes' "System of Surgery," Coote gives the history of a single case, and mentions having seen several others. Erichsen states that the disease, though rare, occasionally occurs, and that he has seen several cases. In Cohen's valuable article on "Diseases of the Mouth and Tongue," in Pepper's "System of Medicine," the observation is made that parenchymatous glossitis is a comparatively infrequent disease at the present time, but numerous ancient writers are referred to as having described it. Bryant details six cases of inflammation and suppuration of the tongue in a paper entitled "The Surgical Affections of the Tongue" ("Guy's Hosp. Rep.," vol. xi., 1883, p. 110), and remarks that, excluding cases resulting from mercurial salivation, the disease is uncommon.

The affection is interesting from a diagnostic standpoint, and important from the fact that it may actually involve danger to life. The nature of a case of lingual abscess may be sufficiently clear, when the symptoms comprise febrile reaction, accompanied by rigors, localized swellings, throbbing pain and fluctuation. In the absence of several of these symptoms, as in the case to be related at the conclusion of this paper, the diagnosis is by no means certain. The presence of an abscess in the parenchyma of the tongue may easily be overlooked, or, acute symptoms being absent, it may be regarded as a lingual tumor of a more serious character. The difficulty of diagnosis is well illustrated in a case referred to by Vogel in "Ziemssen's Encyclopædia" (vol. vi., p. 750). He says that Wutzer mistook an abscess of several weeks' duration for scirrhus, and recommended extirpation. The first incision exposed the error. In a contribution to the London *Practitioner* (1881, xxvii., p. 266), Stephen Mackenzie includes among the conditions liable to be mistaken for glossitis, salivary calculus, of which the notes of two cases are given, acute ranula, of which also two cases are narrated, and herpes of the tongue. Of the last-mentioned rare disease he reports only one case, which was at first regarded as an idiopathic glossitis. A simple cyst of the tongue has on two occasions been opened under the supposition that it was an abscess ("Nouv. Dict. de Méd. et Chir. Prat.," vol. xx., p. 144). The latter condition may even be mistaken for a gummy tumor, especially in the case of an abscess developing slowly and without systemic disturbance. It must be admitted, therefore, that a positive diagnosis is difficult and may be impossible. In some cases an exploratory puncture may be required in order to determine the condition.

An inflamed tongue may become so swollen as to cause alarming and even serious dyspnœa, either by pushing up the velum palati, or, less probably, by pressing down the epiglottis. Glossitis is included by Cohen ("Diseases of the Throat and Nasal Passages") in a list of diseases possibly indicating tracheotomy, and in at least one case on record, death may be referred to abstention from surgical interference. In the London *Lancet* (January 6, 1885, p. 10), J. Z. Laurence reports a case resulting fatally through the obstinacy of the patient's friends in opposing scarification and, later, tracheotomy. The disease occurred in a female in the course of an attack of acute rheumatism. At the autopsy the tongue was found swollen, soft, and infiltrated with sero-pus. An interesting point in the case was "the successive and separate invasion of the two halves of the tongue by the inflammatory action." The left side was first involved, relief being obtained by incision and the evacuation of about half a pint of blood. On the following morning the right half was affected, and further operative interference was denied. It is interesting to notice that the possible necessity of opening the trachea has long been appreciated, although modern views of the risks of the operation itself have undergone decided modification. In the article on glossitis in the "Dict. des Sci. Méd." (1817, p. 494), deep incisions, leeching, and other antiphlogistic measures are recommended, and if the tumefaction of the tongue reaches a degree to cause serious dyspnœa, laryngotomy, "no doubt perilous," is suggested as a last resort.

Dysphagia, as well as dyspnœa, is apt to be an important symptom. Even before the swelling has reached an extreme degree, impediment to the movements of the tongue and pain on attempts at deglutition are decided obstacles to the ingestion of food, and the nutrition of

[1] Presented to the American Laryngological Association and accepted as a candidate's thesis.

the patient is likely to suffer. In a fatal case reported by Ranking and cited by Clarke, the patient died in collapse and "a gangrenous abscess, the size of a turkey's egg, was found occupying the situation of the genio-hyoglossi muscles and the substance of the tongue as far back as the epiglottis," its cavity containing a barley beard, which the patient had placed in his mouth a week previous.

The etiology of lingual abscess is obscure. It is possible that prolonged exposure to wet and cold (Bamberger), in a person of debilitated health, may be sufficient to excite inflammation of the tongue. At least, in non-suppurative glossitis, called by Salter *erectile*, no other cause may be discoverable. On the other hand, a few of the recorded cases of abscess of the tongue are distinctly referrible to traumatism. The idea that simple exposure may be a direct cause of glossitis is opposed by Th. Sidlo, who reports seven cases in the *Allg. Wiener Med. Zeitung* (1879, 8, 9, and 10). He admits that inflammation in the soft parts of the sublingual and submaxillary regions may be excited by chilling of the surface of the body, the process thence extending to the tongue itself. In six of the cases recorded by this observer the whole tongue was affected; in one, only the right margin. In six cases the attack occurred during cold weather, and in four after exposure. The patients were all males and their ages ranged from twenty to forty-four years. An ingenious theory of the etiology of inflammation limited to one-half of the tongue has been suggested by Gueneau de Mussy (*Arch. Gén. de Méd.*, 1879, cxiii., 385), who reports two cases of hemiglossitis. He considers it to be of nervous origin and consecutive to irritation of the chorda tympani. His view is based on the experiments of Vulpian (*Rev. des Sci. Méd.*, 1873, 476; also *Gaz. Méd.*, 1873, 4 to 8), who demonstrated that congestion and swelling of the tongue may be produced by galvanization of the lingual nerve, whereas these phenomena are absent in case of preliminary section of the chorda tympani before its union with the lingual. Gueneau de Mussy prefaces the announcement of his theory by remarking that the nervous supplies to the two halves of the tongue are entirely distinct, while numerous anastomoses occur between the arterial branches of either half, and even the muscular fibres interlace between the two sides. He also claims to find a confirmation of his theory in the occurrence of pain in the ear and side of the head corresponding with the side of the tongue affected. Moreover, the nocturnal exacerbation of pain, with lingual hyperæsthesia persisting through the painless interval, the occurrence of herpetic eruption upon the lips and face, circumscribed erosions of the mucous membrane of the tongue at various points, and, finally, stimulation of the salivary glands, all of which symptoms were noted in the two cases reported by this observer, are thought to support his view of the pathogeny of hemiglossitis. It appears, however, that the structural independence of the two sides of the tongue relates to the blood-vessels almost as definitely as to the nervous distribution. A dense fibrous septum divides the tongue through its middle, and the only points of communication between the arteries are diminutive in size and two in number—one near the tip of the organ and the other in the region of the circumvallate papillæ (Hyrtl). A striking demonstration of this fact has recently occurred in a case of excision of a large part of the right half of the tongue for epithelioma, in which I did a preliminary ligation of the right lingual artery. Hemorrhage from the tongue was comparatively slight and ceased spontaneously, with the exception of a single point near the tip, which was tied, although the ligature did not seem to me to be positively required.

In Allen's "Anatomy" (sect. vi., 626) the statement is found that unilateral glossitis may occur owing to this arrangement of the arteries. So far as anatomical structure affects this theory it may, therefore, be assumed that hemiglossitis is not necessarily neuropathic. Thibierge, who reports a case of right hemiglossitis (*France Méd.* 1882, p. 14), believes the theory untenable. His case occurred in a female, twenty-three years of age, without known cause. The constitutional reaction was exceptionally violent, and several exacerbations or relapses of inflammation occurred before final recovery. Relief was given and suppuration possibly averted by vigorous leeching of the submaxillary region. The result of this method of treatment is looked upon as an argument against the theory of Gueneau de Mussy, on the ground that abstraction of blood from so remote a point would hardly be likely to influence a neurosis of the chorda tympani. It is also noted that in affections of the tongue recognized as primary, especially cancer, aural pain is very pronounced, and is manifestly due to compression caused by the neoplasm or infiltration. In an interesting article on hemiglossitis in the *Liverpool Med.-Chir. Journal* (July, 1883, p. 195), Dyce Duckworth expresses the opinion that this lesion is a "catarrhal neurosis," reflex in character, and not the direct result of exposure, which is merely an exciting cause. In reviewing the nervous physiology of the tongue he calls attention to the fact that both the glosso-pharyngeal and the lingual nerves contain vaso-dilator filaments, those of the latter being derived from the chorda tympani. Vaso-constrictor filaments are found in the lingual nerve itself and in the hypo-glossal nerve. Division of the lingual nerve, before its junction with the chorda, and irritation of its peripheral extremity are followed by contraction, whereas vascular dilatation follows division and irritation of the lingual nerve after it has been joined by the chorda. This author considers the evidence as to the limitation of the morbid process to one nerve not conclusive, but he inclines to a belief in the "involvement of the fifth and chorda tympani branches, or of the glosso-pharyngeal, rather than to that of the hypoglossal." As to exposure as an exciting cause of hemiglossitis, he refers to Hutchinson's idea of the distinction between erysipelatous and catarrhal inflammations in general—in the former the influence of cold may be direct, while in the latter, as in the case of the tongue, it is indirect, and the consequent inflammation is reflex, "the part inflamed not being the part actually chilled, but one in relation with it" (*Med. Times and Gaz.*, January 6, 1883, p. 4). However plausible this theory may seem it needs to be substantiated by fuller and more exact clinical observations.

The treatment of abscess of the tongue, when the condition is well defined, must be perfectly clear. In the formative period, leeching and the use of ice and emollient gargles seem to be capable of aborting the disease. In the event of excessive tumefaction or of suppuration, free incisions on the dorsum of the tongue are demanded. With regard to the danger of this last resource, nearly all the evidence is in the negative. Notwithstanding the extreme vascularity of the tongue, especially in its inflamed state, dangerous hemorrhage seems never to have occurred.

A single case, reported by William Pratt (London *Lancet*, March 11, 1882, p. 389), is of interest in this connection. His patient was a man, fifty-eight years of age. Free scarification was practised for relief of the swelling, and on the following day an abscess opened spontaneously on the under surface of the tongue over the track of the ranine artery. The next day free venous hemorrhage took place into the cavity of the abscess and continued for several hours. It was at length controlled by means of a pledget of lint soaked in perchloride of iron. At the expiration of a fortnight no trace of the abscess remained, except slight induration at its site.

Deep incisions of the tongue not only seem to be devoid of risk, but they undergo repair very quickly, and leave little or no deformity. Still, the use of the knife may be regarded as a last resort, only justified in the presence of a positive diagnosis or of urgent dyspnœa.

In a large proportion of published cases recovery has followed spontaneous rupture, as in those reported by J. H. Pooley (*American Journal of the Medical Sciences*, April, 1872, p. 385) and by Robert Annan (*Medical*

Times and Gazette, October 16, 1852, p. 387). In the former case, a tumor the size of a pigeon's egg was situated at about the middle of the left side of the tongue. It was distinctly circumscribed, denuded of epithelium, slightly sensitive, and gave an obscure feeling of fluctuation. Puncture was proposed but was declined, and the abscess ruptured on the fourth day. In the case reported by Annan, rupture occurred on the fourth day, nine or ten hours after scarification had been resorted to in order to prevent suffocation. The rapidity with which pus formed in this case is rather remarkable, although it may have been present at the time of the incision, the point of the knife, perhaps, not penetrating to sufficient depth. Annan also mentions four other cases of glossitis in his experience, in two of which suppuration occurred. Usually the tongue quickly resumes its normal dimensions after evacuation of the abscess. That this is not always so is shown by the case of Williamson (London *Lancet*, January 22, 1881, p. 136), in which spontaneous opening of the abscess occurred after symptoms had lasted for one week. The tongue remained very much enlarged and protruded from the mouth. The condition seems to have been aggravated by impact of the organ upon the teeth of the lower jaw, and was only relieved by the use of a shield and support made of gutta-percha.

The following case of abscess of the tongue is the only one that has come under my own observation during several years of service at the New York Eye and Ear Infirmary and at the Manhattan Eye and Ear Hospital. Its special interest lay in the marked disproportion between the general and local symptoms, and in the speedy and favorable termination. The patient was a man twenty-two years of age, engaged in a large establishment for making ice-cream. He was somewhat irregular in his habits, but of good constitution, and gave no history of struma or syphilis. He had never had rheumatism, a skin eruption, or other disease. His history was given with difficulty on account of pain caused by attempts to articulate. One week previous he began to have "sore throat," and in the course of two or three days his tongue became so stiff and swollen that he was unable to swallow even liquid food. There were no chills nor fever. On the fourth day swelling and pain on pressure were noticed externally beneath the jaw on the right side, also frequent twinges of acute pain darting toward the right ear. Flaxseed poultices and alum-water gargles were used without benefit. At the end of a week, when first seen by me, there were swelling and sensitiveness in both submaxillary regions, more especially the right. The tongue, except its very tip, was excessively swollen, and its dorsum was covered by a thick yellowish-white fur resembling wet chamois skin. The papillæ were invisible, the surface of the tongue being perfectly smooth. The tip and what could be seen of the under surface were unnaturally red. The leathery fur was quite soft and moist, and there seemed to be an excessive secretion of saliva—at least the patient was unable to dispose of it by swallowing, and it rapidly accumulated in the mouth. Speech was painful and the voice was thick; protrusion of the tongue was impossible. A partial view of the pharynx and left tonsil showed them to be normal. The faucial space was nearly filled by a diffuse swelling of the right side of the tongue, the left side being apparently unaffected. The finger introduced into the mouth discovered the most sensitive region at the base, on the right side and just within reach, but no circumscribed tumor could be defined. Fluctuation was not recognized by palpation internally or externally. The pulse was somewhat accelerated; temperature was normal. The patient was pale and weak from lack of food, not having been able to eat anything for several days. Scarification was suggested, but was objected to, and, accordingly, a calomel purge, warm gargles of borax and chlorate of potash, and warm fomentations externally were ordered. On the following morning a very decided change was apparent. The tongue had nearly returned to its normal size and appearance. The patient stated that improvement began the previous evening with the discharge of a small quantity of matter from the mouth. For the first time in eight days he was able to eat soon after this occurrence. Pain ceased almost immediately and there was much less difficulty in speaking. With a laryngeal mirror a small opening, barely admitting the point of a probe, could be seen at the base of the tongue on the right side. The probe being bent, its curved extremity could be passed into this opening to the depth of nearly half an inch. The margins of the aperture were thick and everted, somewhat resembling an enlarged circumvallate papilla, in the region of which it was situated. On withdrawal of the probe a minute drop of pus exuded. The patient was not again seen after this examination, in which Dr. Asch joined me, and it is natural to suppose that he had no further trouble.

In looking for the cause of the inflammation in this case both traumatism and exposure were found to be concerned. In the course of his occupation the patient was subject to considerable variations of temperature, but he was not conscious of having "caught cold," or of having been ill in any respect for many years. About ten days before the first symptoms developed he was "on a spree" for several days, and may at that time have laid the foundation of his trouble. He also recalled the fact that, at about the same time, while drinking water from a cup, he swallowed a small piece of straw. A fragment not more than three-fourths of an inch long caught in his throat, and he was obliged to dislodge it by using his finger. There was no soreness, pain, nor bleeding, and nothing to indicate that the tongue had been wounded. Still, it is quite possible that a small bit of straw buried itself in the tongue to become the focus of inflammation. As regards this case, it is safe to exclude the neurotic theory of etiology. Many of the symptoms characteristic of a neurosis were absent, and the pain in the ear and side of the head did not present itself until several days after the establishment of inflammatory symptoms.

121 West Thirty-fourth Street.

A NEW OXYTOCIC.

By W. B. ARBERY, M.D.,

WOTASULGA, ALA.

Without any lengthy exordium I will commence my subject by saying that I have discovered an oxytocic which to me is a new and original idea—not having read or heard lectures about it even. It consists simply of heat applied externally. I will briefly narrate a few cases to describe its potency.

I was called to a case of labor, a multipara, five miles in the country, just as daylight had faded. I found the patient walking around in the room, having irregular, short, teasing pains. I had her lie down, and I made the usual digital examination, finding the os quite patulous, with a vertex presentation and a dilatation about the size of a silver half dollar. I folded my arms and waited for several hours, the patient continuing to have the same teasing, irregular pains. I again made an examination to find the smallest possible progress, but there was almost a complete inertia. Getting impatient, and having delivered her twice before, I knew the adaptability of the parts for the required task, and being satisfied there was no *vis a fronte* to antagonize a dose of ergot, I gave it, using a reliable tincture. After a proper interval I repeated the dose, and kept repeating until I had given one ounce, when finding the uterus did not respond, I had the patient walk around the room. Then I kneaded the womb well, and still getting no result I gave ten grains of quinine with a better result from that than anything I had done or given; it roused the uterus to a pretty energetic action for about thirty minutes, then ceased. I then gave a stimulating toddy, but

all to no purpose, and daylight having arrived I hastened home.

In a few hours a messenger came for me in haste to see my patient again. I returned hurriedly only to find the patient plodding along at the same old pace without progressing one jot. Having increased my supply of ergot, I gave another ounce at two doses, but to no purpose. Finally I resolved to go again, but before going I thought of hot mush poultices, and decided to try them awhile to fill up time. I had them prepared nice and stiff, and had them applied over the fundus of the womb as hot as they could be borne, replacing them as soon as one became a little cool. To my great satisfaction, before the third poultice had been applied the pains began to come in full force and regularly, and in two hours after the pains started up, the labor had ended with a fine ten-pound boy. I kept the poultices up until the expulsion of the child.

Second case—a primipara with convulsions ; had four before I saw her. Three miles from town ; found labor just started with a vertex presentation. I gave chloral abundantly, bled her tolerably freely, gave twenty drops of veratrum at intervals, used chloroform inhalations, and still the convulsions would come with the labor progressing only at the minimum rate. It was impossible to use the forceps, and everything being so rigid, close, and compact I could not introduce my hand to turn, so I resolved to hurry nature with my hot poultices, and with my chloroform I stood at the patient's head and had the poultices applied fast and hot. In less that three hours after commencing the poultices, labor was over, with a long-headed, living, fine boy, and no laceration to the mother. She continued to have convulsions for ten hours afterward ; then they ceased and she made a rapid recovery.

Third case—a multipara. I was called out before daylight, found labor barely commenced, but the patient reported as having been worried all night with short, teasing, irregular pains. I waited a few hours with no progress and the same character of pains. About four hours after my arrival the patient inquired what was the matter with her eyes ; said she could not see me nor anyone else in the room. I told her I would remedy that, and gave her a large dose of chloral hydrate. In less than five minutes after taking it she had a light convulsion. I waited half an hour for the effects of the chloral, and then commenced with hot poultices. In four hours I started for home, leaving the mother and child doing well.

Fourth case—a primipara with convulsions. I was called to see her with another physician and requested to bring my forceps and plenty of chloroform. I found a case of puerperal convulsions, having been in labor some five hours, convulsions having commenced in the latter two. The physician had bled her profusely, but it did not have the desired effect of checking the convulsions. The labor had progressed smartly, but after the convulsions set in there was almost a complete inertia—entirely so, so far as the progress was concerned, although she would have short, irregular pains. I advised my hot poultices for awhile rather than any instrumental interference, which advice was acquiesced in and the poultices were applied. They were given without any obvious effect for some time, and I had began to get a little dubious about my hot poultices "at all times and under all circumstances," until I discovered that they were placed near the pubes instead of over the fundus of the womb, and also that they were not hot enough. After correcting the error by putting the poultice higher and having them hotter, good steady pains commenced, and the labor was ended in less than two hours with a still-born babe.

As the cases are somewhat scarce for assistance as detailed above, and my obstetrical practice not being extensive, and being anxious to test the certain utility of my "new idea," I write this to ask the profession to give it a trial and report, since, if it is what I think it is, it is certainly pre-eminently above all the oxytocics for safety and simplicity, as the case can be hastened or slowed at option by simply putting on or withholding the hot applications. I do not mean warm, but hot as can be borne.

THE ETIOLOGY OF THE PLYMOUTH EPIDEMIC.

By WILLIAM STONE TORREY, M.D.,
SCRANTON, PA.

SINCE the appearance of my former article upon this subject, which was contained in the issue of the New York MEDICAL RECORD of June 6th, the press has been filled with communications attacking the position which I assumed and contradicting the statements which I made. It is proper to state that this opposition has been exclusively from the *authors* and *instigators* of the "mountain-stream theory." The facts contained in the previous article were obtained mainly (although not entirely) from the investigations of Dr. Taylor and others, which were embodied in a report made at the instigation of the Plymouth Water Company, and read before a meeting of the Luzerne County Medical Society. That article was intended simply as the expression of my dissent from Dr. Taylor's deductions from admitted facts. The bitterness of the opposition to my theory has compelled me, in self-defence, to make further investigation on my own account, in order that I might avoid the danger of arguing upon erroneous data. This investigation has been carefully prosecuted at the best original sources, and at every step it has tended to confirm the conviction that the "mountain-stream theory" is both inadequate and misleading.
